DR. E. L. MOSS, of the Royal Naval Hospital, Esquimalt, Vancouver's Island, writes us that on the night of Saturday, Dec. 14, an earthquake wave passed through the district at 9.33. A rumbling noise and a quick vibration, causing the windows to rattle, preceded the shock a few seconds. The waves then passed from E.N.E. to W.S.W., causing the wooden house in which he sat to creak and strain like a ship at sea, and leaving an index of their direction in the oscillations of a swinging lamp. He could not detect any accompanying marine wave. The ship's lights were reflected from the surface of the harbour in perfectly unbroken lines. The night was clear, the thermometer at 27°, and there was no trace of aurora. From the *Daily British Colonist* we learn that the shock appears to have been more severely felt on the mainland than on the island. At Olympia and Seattle the shock was very severe, and was accompanied by a slight tidal wave. At Clinton the ground was cracked, and the shock was felt at all the towns on the Fraser. Since 1864 Victoria has not experienced so severe a shock of earthquake.

DR. DUDLEY, of Bogotà, South America, writes that on the morning of Dec. 17 last, at $4^h\ 20^m$ A.M., a smart shock of earthquake was felt at that place, which lasted about 20 seconds. It appeared to move in a S.W. direction. It was sufficiently strong to awaken the inhabitants from their sleep with some alarm.

THE *Times of India* reports a very destructive earthquake which occurred in Sinde on the evening of December 15 last. A succession of shocks took place about 9 o'clock at Shekarpore and other places, followed by a slight shock at about half-past 10. In the town of Lehree, in Eastern Catchi and Zehri, according to one report 200, according to another 500 persons were killed from the fall of houses and walls. The direction of the earthquake was from east to west, with a slightly undulating motion.

ACCORDING to a telegram in the *Times* from Constantinople, February 4, the island of Samos had been visited with successive shocks of earthquake during the previous four days, gradually increasing in violence. Houses have been destroyed, and the affrighted inhabitants of the island are wandering about the open country.

A CORRESPONDENT sends us the following:—"A correspondent in Salvador, in Central America, under date of December 8, writes to the *Panama Record* as follows:—'The volcano which is some six leagues distant from the town of Santana, has dried up a lake which for 500 years or so existed at the base of the craters; but although vast quantities of steam are ejected, and the trees lining the inside of the crater are scorched up and withered, as also are those to a limited distance near the top on the outside, no ejection of lava has yet taken place. The volcano of Isaleo, which was active until quite recently, now shows no sign of life; and the supposition is that some strata which cut off the communication between the two volcanoes have burst through or fallen in, and so changed the channel of the fire. The Government of Salvador intends sending up an exploring party to examine and report on the subject. At the date of the above letter, no change had taken place in the volcano.

MR. HARDING, senior wrangler at Cambridge, has been declared first Smith's prizeman; while the second prize has gone to Mr. Nanson, the second wrangler.

WE have received a paper by Prof. Theodor von Oppolzer on the comet discovered by Pogson on December 2, following the telegraphic hint of Prof. Klinkerfues. Prof. Oppolzer enters into an elaborate series of calculations to prove that the observed comet was intimately connected with the star-shower of November 27, and that in all probability it was one of the heads of Biela's comet.

A REPORT, coming of course from America, has been going the round of the papers that Prof. Tyndall has been coining money by thousands from his lectures in the United States. Dr. Bence Jones writes to *Les Mondes* of January 30, giving the facts of the case, as told by Prof. Tyndall himself. His expenses in America, partly caused by the death of "poor Millard," his assistant, have been very high. There still remains, however, Prof. Tyndall says, 2,000*l*. This sum he intends to devote, in consultation with Prof. Henry of Washington, to the promotion of some worthy purpose in America.

WE are glad to see that a new edition of Chambers's *Information for the People* is about to be issued. The first edition was issued in 1833, and the last in 1857, since which, science in all

its departments has made such rapid strides that scientific treatises published sixteen years ago must now be considered seriously defective and in many cases absolutely misleading. We are therefore glad to see from the prospectus that the scientific treatises have been entirely recast, so as to be adapted as nearly as possible to the present state of knowledge, and we have reason to believe that the various articles have been put into the hands of men who are acknowledged masters of their several subjects. Indeed we think it a sufficient guarantee that the work will in every respect be up to the mark, that the editorial supervision has been entrusted to Dr. Andrew Findlater, who has already deservedly won himself so great credit as Editor of Chambers's *Encyclopædia*; science at least is likely to have fair play in his hands. This work has already done much good in spreading accurate and valuable knowledge among the people. We hope the new edition will have as wide a circulation as its predecessors among the classes for whom it is adapted.

A SUPPLEMENTARY number of *L'Institut* has been issued, containing reports of the French Academy from September 5 to December 26, 1870, during which time, on account of the investment of Paris, the publication of the journal had to be suspended. Besides the French Academy, it contains reports of the Royal Society, the Berlin, Munich, and St. Petersburg Academies of Science, and the Göttingen Society of Science for the same period.

WE have received the "Report of the Birmingham School Natural History Society" for the year 1872, and a very satisfactory one it is. The society was founded in 1869, under the auspices of the Rev. C. Evans, Head Master of the school, since which it has made very creditable progress. Liberal grants have been made by the governors of the school for the purchase of books on Natural History, and the library contains several standard works. In 1871 a museum was fitted up, and during the past year three sections have been formed—botanical, entomological, and geological; and it is hoped that, eventually, new sections will be formed for the study of other subjects, such as physiology, zoology, &c. Three excursions have been made during the year, and there would have been several more, had it not been for unfavourable weather. The report contains some very creditable papers by the youthful members of the society, and we hope that future reports will contain the results of original observations on the part of the members.

FROM the report of the Grant Medical College, Bombay, we learn that during 1872 the total number of students was 283, showing an increase of 37 over 1871. Great improvements have taken place in the Museum, and Dr. Sylvester, the officiating principal, says, that for the last twenty years it has not been in such good order as it is at present. Dr. Sylvester reports that the system of education is not so sound and deep as it ought to be, and wisely reccommends that some subjects should be omitted from the course, and a more strict and penetrating knowledge insisted on in the others. He also seems to think that more care ought to be exercised in the appointment of professors, and that a sort of supplementary professor should be appointed to each chair, who would be ready at any time to undertake the duties of the professorship in case of a vacancy.

WE are glad to notice that the evening lectures to working men at the school of Mines have been eminently successful. The 600 available seats are all occupied, and about 600 more applicants have been necessarily refused. Those who attend are all *bona fide* working men, who in various ways show that they appreciate and understand the scientific lectures delivered. Each professor gives a course of six lectures every other year.

EARLY on Saturday morning a fire broke out in the Royal Military Academy at Woolwich, which terminated in the total destruction of the large central block of the building. A foul flue is supposed to have been the cause of the fire. The damage is estimated at 100,000*l*.

THE principal paper in *La Revue Scientifique* for February 1 is a long analysis of Darwin's Descent of Man, which has recently been translated into French. The writer endeavours to give a perfectly fair view of the work, but the tone of the article shows that Darwin is beginning to be better understood and appreciated in France than he has hitherto been. The writer sees in Darwinism a gigantic effort of the human mind to arrive at an explanation of phenomena which had previously been regarded as beyond the human grasp. He thinks it the duty of every naturalist, whatever may be his leanings, to study the facts and theories put forth by Darwin.

WE have received the prospectus of a German work likely to be of considerable interest and value—a history of Writing ("Geschichte der Schrift und Schrifttums," &c.) and written characters, symbolical and otherwise, from its earliest beginning in the shape of tattoo marks, down to the signs used in modern telegraphy, including an account of the modes of writing among all the nations of the world, savage and civilised. The specimens of the illustrations sent us are carefully executed; one of them represents a man, most elaborately and minutely tattooed from the crown of his head to the tips of his toes. The author is Heinrich Wuttke.

WE noted some time since that the French Government contemplated suppressing the *Bureau des Longitudes*, in order to save its expense to the nation. The French Academy has made a vigorous and indignant protest against such a philistian proposal. The protest recounts the glories which have in former times accrued to France from the discoveries of its eminent astronomers, shows the important position formerly held by the *Bureau*, the valuable assistance it has given to astronomy and navigation by means of its journal, the *Connaissance des Temps*, and declares that by degrees in recent years, the means of doing efficient work have been withdrawn from it. Since 1854 the *Bureau* has ceased to have the control of the Observatory. The Academy demands that instead of suppressing the institution, Government should restore to it the means of making itself more useful.

THE first number of an illustrated paper printed in Japanese, *Tai Sei Shimbun*, or *Great Western News*, was published in London on January 15. Its object is to clearly reflect the opinions of Japanese who have seen the world and learned European languages for the benefit of their countrymen at home. It is edited by a Japanese resident in London, in conjunction with Prof Summers, of King's College.

A CORRESPONDENT writes asking us whether any Alpine walker among our readers has had experience of Sir T. Troubridge's knapsack, the weight of which is borne principally upon the pelvis instead of on the shoulders, thus leaving the chest more free. Also where it can be obtained.

WITH the commencement of volume lxxxi. of *Astronomische Nachrichten*, the office of that journal will be removed from Altona to the Observatory at Kiel, to Prof. C. A. F. Peters, at which address all communications should be sent.

NO. 1917 of *Astronomische Nachrichten* is mainly occupied with letters from various quarters on the star-shower of Nov. 27, 1872.

To No. 1919 of *Astronomische Nachrichten*, Prof. Spörer contributes the results of observations on the distribution of sun-spots for the periods of rotation, vi. and vii., for the year 1871.

SIR BARTLE FRERE and suite arrived at Zanzibar Jan 12.

NORTH Africa is at present overrun by exploring expeditions. The latest news from Sir Samuel Baker is contained in a telegram dated Khartoum, Nov. 7, 1872. According to this he left Gondokoro in 1871 for Kimrasi, but from the hostility of the natives was compelled to return some distance. In consequence of the prolonged absence of Sir Samuel, we learn from *Ocean Highways*, the Viceroy of Egypt decided upon sending a relief expedition of sixty-five men under the command of Colonel Purdy, an American officer in the Egyptian service. The plan is to start from Mombas and to make a journey to the supposed position of Baker, above Gondokoro. If the expedition is successful, very important geographical results may be expected from the route to be taken by Colonel Purdy, which will lead him across the Victoria Nyanza region.

Ocean Highways for February contains the first part of an article by Dr. Beke, entitled, "Position of the Sources of the Nile," his object being to show the influence which Ptolemy's determination of these sources has had on later geographers, down even to Livingstone, who adheres essentially to Ptolemy's opinion. The almost unanimous conclusion, however, come to by geographers of the present day, Dr. Beke tells us, is that the rivers described by Livingstone are tributaries of the Congo, and that the numerous sources described by him as the great water-parting of Southern Africa, are those of that river, and not of the Nile.

COMANDATORE NEGRI is making satisfactory progress in his endeavour to enlist Italian public opinion in favour of an Italian Arctic expedition.

THE first number of *Kosmos*, an Italian geographical bi-monthly journal, edited by Guido Cora, has just appeared.

IN NATURE for Jan. 23, we noted the supposed discovery of a great Arctic Continent by M. Pavy. The story appeared many weeks ago in the *Scotsman*, which took it from "the American papers." We, however, took no "note" of it till a similar account appeared in the *Times* a week or two ago, when we noted it with some expressed distrust. According to *Ocean Highways*, the story, as we feared, turns out to be, in all likelihood, a hoax. The French Geographical Society have received no such report as the American papers say has been transmitted to them. Far from M. Pavy having reached Wrangell Land, there are now doubts whether the expedition will start at all.

WE learn from the *Athenæum* that Sir John Lubbock is preparing a Bill, to be brought forward early this session, having for its object the preservation of the megalithic monuments to the United Kingdom.

WE have received the first number of the *Journal of the Women's Educational Union*, the main purpose of which is to promote the very commendable objects of that Union.

FROM pamphlets and periodicals before us we cull the following notes:—Dr. Hollis's *Astronomical Almanack* for 1873 contains a large quantity of very valuable and well-arranged information, which will be found useful to the rapidly increasing number of amateur astronomers, and to those who do not possess or who shrink from consulting the "Nautical Almanack."—The *Garden* learns that the celebrated Jardin Fleuriste of the city of Paris, which since the war has been in a ruinous condition, is at last to be entirely abolished, and the ground whereon it stood let for building purposes. A few years ago it was one of the most interesting and instructive gardens in existence.—The principal articles in the *Journal de Physique* for January are a review of the fundamental theories relative to electro-dynamics and induction, by M. A. Potter: one by M. Berthelot on Calorimetric thermometers, in which he expounds the results of his studies on the subject for a number of years past: and a short one by M. C. Decharme, giving the results of a number of experiments to show the rate at which different liquids ascend a capillary tube.—A French newspaper, the *Monde*, contains a justly laudatory article on the Abbé Moigno's *Salles du Progrès*, which it seems are being more and more taken advantage of by the Parisian middle classes.—The "Annuaire de l'Academie Royale de Belgique," besides a mass of valuable information concerning the Academy, contains memoirs of a number of deceased Academicians, including one of the late Mr. Babbage, who was an associate of the Academy.—The *Penn Monthly* (Philadelphia) for May, July, August, and September, contains a series of articles by Mr. Edward D. Cope, on "Evolution and its consequences," in which is expounded the theory of evolution so far as it concerns animals and plants.—We have received a reprint from the *Quarterly Journal of the Geological Society* of the admirable paper "On the Evidence for the Ice-sheet in North Lancashire and adjacent parts of Yorkshire and Westmoreland," by Mr. R. H. Tiddeman, M.A., F.G.S., of the Geological Survey. It is accompanied by a well constructed map.—An address delivered before the Chemical Society of the Lehigh University, by Dr. B. Silliman, on "Deductive and Inductive Training," contains a very interesting history of the two systems from the earliest times to the present day.—A translation of Prof. Donati's oration at the inauguration of the new observatory at Florence, October 27, 1872, appears in the *Astronomical Register* for February.

ON THE COAL QUESTION *

THE North of England Institute of Mining and Mechanical Engineers was, in its origin, a society limited in its scope to the discussion of subjects belonging to the practice of mining, and especially of coal mining. At that period the working of coal and other minerals was carried on with less aid from machinery than at present, and the district in which the society is located was not so distinguished as it now is for the practice of mechanical engineering in all its branches. Hence, the society, in its growth, has gradually assumed more and more of an engineering character; and my recent election, as your president, indicates that mechanical science is no longer regarded by the members as secondary, or merely subsidiary, to the practice of mining. But we must guard against this tendency of the engineering element to outgrow the mining element of this institute. We must not forget that we are situated in the very heart of the coalfield which, more than any other, has rendered England pre-eminent as a producing nation, and that, notwithstanding the increasing magnitude and importance of the engineering works of this district, the raising of coal is still foremost amongst the industries of the North, both as regards the extent of the interests involved, and its importance to the general prosperity of the nation.

For these reasons, although I come before you as the first president of this society elected from the ranks of mechanical engineers, I shall, in this address, make coal the principal topic of my remarks, including, however, mechanical applications associated with its use or involved in its production. As I shall speak of coal in an economic as well as in a technical point of view, I cannot well avoid making some reference to its present excessive cost, because coal, like everything else, must be governed in the extent of its application by its price in the market. In addressing an institution, so largely composed as this is of colliery proprietors, it is not an agreeable task to dwell on the evil of dear coal; but our institution is not a commercial one, and I must speak of this subject, not as affecting individual interests, but as bearing upon mechanical art and national prosperity. For many years past the consumption of coal has been increasing at the rate of about 4 per cent. per annum, computed in the manner of compound interest. We are all familiar with the cumulative effects of compound rates of increase; and it is easy to see that if the consumption of coal continued to advance at this rate, we should speedily arrive at impossible quantities. Thus in 18 years our present enormous consumption would be

* Inaugural Address by Sir William Armstrong, C.B., President of the North of England Institute of Mining and Mechanical Engineers, delivered at Newcastle, February 1.

doubled; in 36 years it would be quadrupled; and in 54 years it would be eight times greater than at present. It is clear, therefore, that our consumption has been increasing at a rate which could not possibly last. If nothing else was destined to arrest it, a failure of mining labour was inevitably approaching to have that effect; but a few years would probably have yet elapsed before the number of hands became inadequate to meet the required demand, had not the miners precipitated the event by restricting the hours of work. The hours of mining labour in this district 25 years ago were 9 per day. At a subsequent date they were reduced to 8, then to 7, and finally to 6. Hitherto, the men have worked 11 days a fortnight, but it seems doubtful whether more than 10 can now be worked consistently with the very proper limitations of the recent Coal Mines' Act, in regard to the labour of the boys. The full hours per fortnight will, therefore, at the most, be 66, or 33 hours per week of labour at the face of the coal; but as it is only the steadiest men that work full time, the average time will, of course, be considerably below that limit.

I am not aware to what extent reduction of time has been carried in other parts of England; but we hear of the same policy of restriction, either of time or output, or of both, being put in practice in all the important coal districts. I do not suppose that the average output, per man, has fallen off proportionately to the reduction of hours. The men work hard, even harder than formerly, while at their post, but it is impossible that so great a reduction of working time can have taken place without so lessening the output, per head, as to neutralise in a great degree the increase of production due to the numerical growth of the mining population. Under these two conditions of increasing consumption and restricted labour, we have reached a point at which the demand has overtaken the supply. As yet, the deficiency cannot be great, for it has only very recently become apparent. Consumption does not advance by jumps; and we may assume that if a progressive increase of four or five per cent. per annum could have been maintained in the production of coal, a balance would still have existed between supply and demand. Though production has ceased to keep up with demand, it has not, so far as we can judge, actually receded, and it would therefore appear that a small addition to the present supply would restore the equilibrium. But small as the deficiency must be, it is sufficient to create a sense of scarcity, and as a consequence, to send up coals to a famine pitch.

The situation is a grave one, and the public has not yet fully realised how very grave it is. Taking the present consumption at 110 millions of tons (exclusive of exportation) and estimating the extra price to consumers at 8*s.* a ton over all, the annual loss to the community from the additional cost of fuel, amounts to 44 millions sterling. Had a Government tax of 44 millions been levied upon coal, in addition to existing taxation, the effect would have been regarded as utterly ruinous, not only in regard to its prodigious amount, but on account of its repressive effect upon every kind of production. Yet it is a fact that we are now paying the equivalent of such a tax, with this unfavourable difference, that the money does not go into the coffers of the nation. Whether it chiefly goes to coal-owners or coal-miners is a question which I need not discuss, but I may observe that the restrictive action of the men has benefitted their employers as well as themselves, and that the public are the only sufferers. Coal-owners have long been aware that limitation of quantity was the only effectual mode of raising price, but they have never been able, by their own action, to maintain a restricted production. At last their workmen have done it for them, and we see the result.

Whether the trade of the country will bear up against the heavy burden of dear coal, combined as it is with dearness of other products, arising from similar causes in other industries, is a question on which I shall not attempt to prophesy. It will be more to the purpose to consider what can be done to mitigate the evils under which the nation is now labouring in regard to the price of coal. It is vain to appeal for relief either to coal-owners or coal-workers. Self-interest is the ruling principle of trade, and it is visionary to expect that men will sell either labour or the produce of labour for less than the market price. However generous a man may be, he will not exhibit his generosity by selling an article below its value. Speaking then, as one of the public and not as a coal-owner, I say, we must strive to economise the use of coal; speaking as president of an institution of mining and mechanical engineers, I say, we must endeavour to make up for the deficiency of human labour by a more extended use of machine labour. The waste of coal, both in domestic and manufacturing use is a threadbare subject, but there never was a time when its consideration was of so much importance as at present. The small deficiency of supply which is now so violently stimulating the market would be just as effectually expunged by economising consumption as by increasing production. If, on the one hand, the mining population could easily, by a few hours' addition to their weekly labour, restore the equilibrium between supply and demand, so on the other hand consumers taken as a body, could do the same thing, by discontinuing in a small degree those reckless habits of wasting coal to which they obstinately adhere.

The consumption of coal takes place under three great divisions, each absorbing about one-third of the whole produce:—(1) domestic consumption; (2) steam-engine consumption; and (3) iron making and other manufacturing processes. In the first two divisions the waste is simply shameful; in the third it is not so great, but still considerable, though in some processes, and especially in the smelting of iron, economy of fuel has been so diligently pursued that there remains but little apparent scope for further saving. I shall not dwell on the waste of coal in domestic consumption, as it is scarcely a subject for engineers; but the circumstances of the times are such as to forbid my passing it unnoticed. It is impossible to conceive any system of heating a dwelling more wasteful than that of sinking the fire-place into a wall directly beneath the chimney which carries off the products of combustion. Nothing can be clearer than the advantage to be gained by merely advancing the fire-place a little into the room, and constructing it with proper heating surfaces, as in the "Gill-stove," and many other stoves acting on the same principle. There is no occasion to shut out the fire from view. Neither is there any difficulty about ventilation, since fresh air can easily be introduced from the exterior by a pipe delivering its supply against the heated plates, so as to temper the air before it enters the room. By this simple and unobjectionable departure from the conventional fire-place, the quantity of coal required to produce a given heating effect might easily be reduced to one-half, and still greater economy would be effected by the use of hot-water apparatus, which, however, has the objection of being too costly in first outlay to admit of very general application. For cooking purposes also, the consumption of coal is in most houses equally extravagant, and I may add, equally inexcusable, since the means of prevention are attainable by the adoption of known methods and appliances for concentrating the heat upon the work to be done.

A more appropriate subject for the consideration of this institution is the wasteful employment of coal for steam power. The steam engine is, at best, a very imperfect machine for utilising the mechanical power of heat, for in no case do we realise more than about one-tenth of the theoretical effect of the fuel. But the difference in economy between our best steam engines and our worst is enormous, and unfortunately by far the most numerous class belong to the category of the worst. In the best kind of engines, the consumption of coal per horse-power is rather less than 2 lbs., but there are thousands of steam engines in daily use which burn from 12 to 14 lbs. per horse-power. This excessive wastefulness arises from defects, both in the mode of raising the steam and in the mode of applying it. Theoretically, 1 lb. of coal is capable of evaporating 13 lbs. of water, but the conclusion arrived at on this subject by the late Royal Commission on the duration of coal was, that in practice 1 lb. of ordinary coal did not, on an average, evaporate more than 4 lbs. of water. The causes of this deficient result are perfectly understood, and, therefore, cannot be excused by ignorance. They are—insufficient boiler surface to absorb the heat, insufficient steam space to allow of a complete separation of the steam from the water, unclothed boilers, and imperfect combustion of the fuel, arising from badly constructed furnaces and from bad firing. The defects in the mode of applying the steam, or in other words, the defects which belong to the engine, in contradistinction to the boiler, are equally well known and equally remediable. The steam—to begin with—should be taken from the boiler at a much higher pressure than is usual. It should be admitted upon the piston at the full boiler pressure, and allowed to expand in the cylinder until its power is practically exhausted. The cut-off valves should be close to the end of the cylinders, as in the Corliss arrangement, so as to leave the smallest possible amount of space between the valve and the piston when commencing its stroke. Finally, the cylinder should be steam jacketed to prevent its cooling during the

expansion of the steam, and thereby causing condensation on the next admission of steam. Nobody disputes these requirements of a good engine, and yet how few engines there are in which these conditions are fulfilled. The responsibility, however, for this waste of coal lies more with the users than with the makers of steam engines. Old-fashioned engines are retained in use partly on account of the outlay involved in replacing them, and partly from a dread of novelties and refinements requiring more care and delicacy of treatment than steam engines commonly receive. Even in replacing old engines the repugnance to any increase of first cost, and the distrust of departure from long-tried patterns, powerfully tend to a conservation of antiquated types of steam engines. As an encouragement to those who contemplate reforming their engine power, I may state what my own experience has been of the advantage of so doing. The engines and boilers originally applied at the Elswick Works, though representing a fair average of efficiency, were of the simple description then almost invariably used in factories. My firm, like others, was naturally averse to changing them on account of the expense of so doing; but about two years ago they determined to begin the renovation of all their old engines by putting down, as a first instalment, two large engines of the Corliss pattern to do the work previously performed by ten smaller engines. These two Corliss engines are now both at work. They have boilers of the best construction, and are fitted with various accompaniments favourable to economy of fuel, including Jukes' arrangement of mechanical firing. One of these engines uses twenty-four tons of coal per week against sixty tons used by the engines it has superseded. The other appears to be doing equally well, but I have not the necessary data for making a similar comparison. Assuming the economy effected to be the same in both cases, the aggregate saving of coal amounts to seventy-two tons per week. The number of firemen required is also much diminished, and the general result is, that, notwithstanding the enormous rise which has taken place in the price of coal, the required steam power is now obtained at a less cost than before, after allowing for interest on the capital expended.

Thus, then, the consumers of coal, as well for domestic use as for steam engines (under which two heads about two-thirds of our own consumption are comprised), have it in their power to economise their use of coal to an enormous extent, without any diminution of effect. In metallurgical and other manufacturing processes there is also room for much saving of coal; but I must not extend my observations into that division of the subject. Speaking generally of coal consumption in all its branches, there can be little doubt that without carrying economy to its extreme limits, all the effects we now realise from coal could be attained with half the quantity we use. If a reduction to that, or any approximate extent were effected, we should hear nothing more of scarcity or prohibitive prices for many years to come.

And now as to the practicability of economising human labour in coal mines by the employment of machinery. Much has already been done in applying machinery for the underground traction of coal, and a great reduction has thereby been effected both in men and horses; but the cutting of the coal is still almost exclusively performed by human labour. The service is a hard and dangerous one, and as it requires skill and experience, it is not easily taken up by untrained men. In every point of view, therefore, there is the strongest inducement to substitute mechanical appliances for manual labour in the process of cutting coal. Many attempts have been made to make a machine do the work of a man in this kind of labour, but with only imperfect success; and yet the problem does not appear, upon the face of it, to be one of very difficult solution to persons accustomed to mechanical invention, and thoroughly acquainted with the conditions under which the work has to be performed.

What is wanted, is a machine capable of cutting a groove at the base of the coal, so as to allow the superincumbent mass to be easily dislodged. The mode of cutting may be by hewing, by slotting, by sawing, or by scooping. The machine must travel along the face of the coal so as to follow up its cut. It should have a long face to work at, so as to avoid frequent stops and changes, and for this purpose the long-wall system of working must be adopted. The difficulty of supporting the roof may, in some cases, be an impediment to the adoption of the long wall system, but I believe the cases would be few in which the difficulty would be insuperable.

Then, as to the power for driving the machine: that must clearly be compressed air transmitted from a steam-engine at the surface, as is now actually practised for the propulsion of all forms of these machines. Compressed air is not an economical medium for transmission of power, partly because the power expended in its preliminary condensation is not recovered by corresponding expansion in the exercise of its power, and partly because much of the force exerted in compression takes the form of heat, which is dissipated during the transmission of the air. In other respects compressed air is peculiarly adapted for conveying power into a mine, because, unlike water, it requires no provision for its removal, and actually helps to supply the necessary ventilation. This is a fair statement of the nature of the work to be done, and of the conditions under which it must be performed. Whatever difficulties there may be must be of a nature capable of being surmounted by mechanical skill and careful observation of the impediments to be overcome. Partial success has already been realised, and I confidently look forward to a time when, to the many services which we exact from coal as a source of motive power, we shall add the cutting of the parent material from the solid beds in which it is deposited.

But it is not alone in coal-mines that the extension of machinery is called for. The dearth of labour is being felt in every department of industry, and we have to fear on the one hand a ruinous collapse of trade, or on the other a continued rise in the price of all productions, threatening to neutralise the advantage of high wages, and impoverish persons dependent on fixed incomes. The only hope that I see of escaping one or other of these alternatives is by increasing the use of machinery and diminishing the direct employment of men. It is in the interest of working men, as well as of all other classes, that we should throw the burden of our wants as much as possible upon inanimate power; and it is a high function of mechanical science to relieve man from that description of labour which consists in the exertion of mere animal force, and leaves him more free for the exercise of skill which is beyond the province of machinery.

One of the worst effects of dear coal is that it involves dear iron. Coal may be economised, but iron cannot, without positive loss. Production of every kind, as also steam navigation and railway transport, are essentially dependent upon the use of iron as well as of coal. Hence, dear iron, like dear coal, is a burden, both on manufacture and on commerce, and its dearness diffuses itself over every article which we derive either from foreign trade, or from home manufacture. But although the present high price of iron is chiefly due to the scarcity of coal, it is not wholly so. The dearness of labour employed in its production is also telling seriously upon its cost, and the importance of substituting some system of mechanical puddling for the present laborious process is daily becoming more apparent. Many inventions for attaining this object have been tried, but no substantial success was realised, until Mr. Danks produced his rotating furnace in America. If Mr. Danks' success be confirmed by continued trials, he will have conferred an immense benefit, both upon the makers and the consumers of iron. Unhappily for him, the general ideas embraced in his apparatus appear to have been suggested before, and although he has the great merit of having shown how the previous ideas on the subject can be rendered available, the patent laws do not afford him that protection which they so lavishly bestow upon others who have accomplished no practical result. Under an equitable and discriminative system of patents, Mr. Danks would have obtained a monopoly as due to the importance of his invention, notwithstanding the abortive attempts of others to reduce the same ideas to successful practice. It is to be hoped that advantage will not be taken of Mr. Danks' unprotected position to deprive him of an adequate reward.

Having spoke of steam engines in reference to the great defects of those in most general use, it is only fair that I should acknowledge the great improvements which are exhibited by nearly all classes of those engines in their most modern forms. Mr. Bramwell, in his recent presidential address to the Mechanical Section of the British Association at Brighton, points out with justice how much has recently been done to improve the efficiency of marine, locomotive, and agricultural engines, and urges the importance of carrying out to a still greater extent the application of those principles which have already been productive of so much advantage. To this recommendation I may add that we must not neglect to follow up any new line of improvement which the progress of discovery may present to us.

(To be continued.)

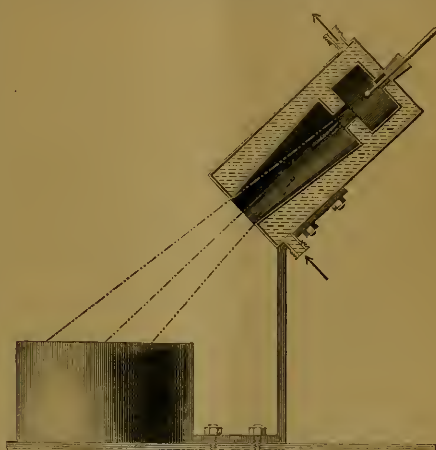
RADIANT HEAT

LORD ROSSE has shown* that the diathermacy of flame cannot be determined by the method described by Mr. W. Mattieu Williams, in his communication to NATURE, vol. vi. p. 506. Referring to the discrepancy which the reader may remember that Mr. Williams pointed out, Lord Rosse says: "The explanation of the discrepancy seems to be that the radiant heat from a flame, like that from any other body, varies as the inverse square of the distance and therefore the total effect is proportional to $\frac{1}{d^2} + \frac{1}{d'^2} + \frac{1}{d''^2}$ + &c., not $\frac{1}{d} + \frac{1}{d'} + \frac{1}{d''}$ + &c., where *d*, *d''*, &c., are the distances of the flames from the thermometer; in which latter case the order of lighting the jets would answer the desired object."

Mr. Williams, in order to meet the objection raised, presents calculations based on the assumption that the mean distance between the seventeen small flames and the thermometer is 14 in. The space from centre to centre of the flames being $\frac{1}{4}$ in., the distance between the thermometer and the centre of the nearest flame will be 12 in. Evidently Mr. Williams is not aware that a thermometer placed at a distance of 12 in. from his cluster of diminutive flames, cannot indicate 53° C. (127·4° F.), unless the surrounding atmosphere be heated to a temperature exceeding 123° F. Had he ascertained, experimentally, that the radiation of a cluster of such feeble flames, at the distance of 12 in. from the thermometer, imparts a temperature less than 3° C. above that of the atmosphere, he would no doubt have admitted the correctness of Lord Rosse's explanation of the supposed discrepancy, as freely as he admits the correctness of the theory on which that explanation is based.

The subject having attracted much attention, the writer has deemed it necessary to institute a series of experiments in order to test the accuracy of the table of temperatures which Mr. Williams desires Lord Rosse to accept on the ground that "the maximum error is less than $\frac{1}{10}$ of a degree, and the mean error lies between that and $\frac{1}{78\frac{1}{4}\cdot 25}$ of a degree."

Before entering on an examination of the result of the experiments adverted to, it will be necessary to call attention to the fact that, the transverse sectional area of a flame produced by 17 jets arranged in a straight line, $\frac{1}{4}$ in. apart, consuming 5 cubic feet of gas an hour, corresponds with the area of a circle of 0·87 in. diameter. The distance between the nearest point of the flame and the thermometer being 12 in., it will be found on calculation that the mean angle subtended by the heat rays projected towards the thermometer will be 4° 9′. Agreeably to the laws of radiation, the temperature produced at a given point by the heat rays projected from a deep radiating body, depends on the mean angle subtended. It may be shown, therefore, that in order to produce the differential temperature of 53° — 19° = 34° C. (61·2° F.), observed by Mr. Williams, the intensity of the flame must far exceed that capable of being developed by any chemical means. A brief explanation of this important subject will be proper in this place. The accompanying illustration represents a pyrometer constructed by the writer for measuring with desirable precision intensities of all degrees. The pyrometer consists of a conical vessel communicating with a cylindrical chamber, as shown in the sectional elevation, both being surrounded by an external vessel through which a current of water, of uniform temperature, is circulated. The thermometer for registering the temperature produced by the radiation of any incandescent body, is inserted in the cylindrical chamber at a fixed distance from the opening of the conical vessel; hence the angle subtended by the heat rays projected by the radiating body towards the bulb of the thermometer, will remain constant whatever be the distance of that body from the instrument. Of course the radiation must be large enough to cover the entire field contained within the radial lines drawn from the bulb through the circumference of the opening of the conical vessel. We have already adverted to the fact that the temperature transmitted to the thermometer depends on the subtended angle. Consequently, by ascertaining practically what degree of temperature is imparted to the thermometer of the pyrometer, by a radiator of *known* intensity, we can determine the intensity of any other radiator by merely observing the temperature it imparts to that thermometer. It should be stated that in the pyrometers which have been constructed, the diameter of the opening of the conical vessel is $\frac{1}{5}$th of the distance from the thermometer; hence the angle subtended is very nearly 11° 26′ Experiments made with an incandescent block of cast-iron, arranged as represented in the illustration, have shown that when the temperature of the block is 1930° above that of the surrounding atmosphere, the thermometer of the pyrometer indicates a temperature 20·7° higher than the circulating water in the casing. Applying the pyrometer in a similar manner, for ascertaining the temperature of a mass of overheated fused cast-iron, the indication of the thermometer has been found to reach 31·4° above that of the water in the enclosure. Now, the temperature of radiators is proportional to the radiant heat which they transmit, provided the subtended angles be alike; hence it follows that the temperature of the fused metal must be $\frac{31\cdot 4 \times 1930}{20\cdot 7} = 2940°$ above that of the water in the casing surrounding the conical vessel. Adding the latter temperature, viz. 60°, we ascertain that the actual temperature of the fused metal will be very nearly 3000°. The result of several experiments shows that this temperature corresponds with that determined by the practical expedient resorted to during the investigation, of melting wrought-iron in the fused mass. It should be mentioned that in



Pyrometer for various intensities.

constructing the scale of the new pyrometer, the radiant power corresponding with given subtended angles and given temperatures, has been ascertained with critical nicety by experiments conducted within a vacuum. For the purpose of demonstrating that the distances assumed by Mr. Williams in his reply to Lord Rosse are greatly exaggerated, a reference to the amount of radiant heat transmitted to the thermometer by the fused metal will no doubt be most convincing. We have before stated that the heat rays projected towards the thermometer from a flame produced by seventeen gas-jets subtend a mean angle of only 4° 9′, while the heat rays projected from the fused metal towards the thermometer of the pyrometer, subtend an angle of 11° 26′. The areas corresponding with these angles being $4\cdot 15^2 : 11\cdot 43^2 = 1 : 7\cdot 6$, it follows that, unless the intensity of the gas flame is $3000° \times 7\cdot 6 = 22800°$ F., it cannot transmit to the thermometer the same temperature as the fused metal, viz. 31·4° F. But Mr. Williams records an increment of temperature of 53° − 19° = 34° C. (61·2° F.); hence $\frac{61\cdot 2 \times 22800}{31\cdot 4} = 44723°$ F., must be the temperature of his flame, if twelve inches be a true distance.

Having thus proved by demonstration that the distances assumed by Mr. Williams are exaggerated, let us now briefly examine the result of the experiments which have been made with an apparatus constructed agreeably to the description contained in his original communication. In carrying out these experiments, it was deemed necessary, before inserting the recording thermometer in a box as directed, to expose the same to the radiant heat of the flame, freely suspended in the atmosphere

* NATURE, vol. vii. p. 28.

but carefully protected from currents of air by screens appropriately arranged. The horizontal gas-pipe with its perforations, ¼ inch between each, having been so adjusted that the distance between the central perforation and the thermometer was 14 in., the 17 jets were ignited, and the supply of gas regulated at precisely 5 cubic feet per hour. The temperatures imparted to the thermometer during the experiment are recorded in Table A. It

TABLE A.

Time.	Indication of Thermometer.	Temperature of surrounding Atmosphere.	Differential Temperature.
m. s.	Deg. Fah.	Deg. Fah.	Deg. Fah.
0 0	62·8	62·8	0·0
6 2	64·4	62·8	1·6
12 5	65·6	63·0	2·6
18 6	66·5	63·2	3·3
24 8	67·0	63·4	3·6
30 11	67·3	63·6	3·7
36 9	67·4	63·7	3·7

will be seen on examining this table that the temperature imparted to the thermometer at the expiration of 36 minutes, was only 3·7° F., in place of 61·2° observed by Mr. Williams; the rate of discrepancy being thus 3·7 : 61·2 = 1 : 16·56.

This extraordinary discrepancy between the temperatures published by Mr. Williams in his original communication, and the distances assumed in his reply to Lord Rosse, having been fully established by the experiment, the arrangement was changed, the thermometer being brought within 3 in. of the flames. But even at this short distance, the thermometer exposed to the radiant heat during an interval of 29 minutes, indicated a differential temperature of only 22·6° F., in place of 61·2° F. as stated by Mr. Williams—a fact clearly showing that the high temperature observed by him was owing to the intervention of the box in which he inserted the thermometer. Such a box composed of polished tin plate, open at the end presented towards the flame, was accordingly applied; its position being such that the space between the thermometer and the flame measured 3 in., as before. The 17 jets being ignited and the supply of gas regulated at 5 cubic feet per hour, the column of the thermometer rose rapidly, attaining a height of 136° in 20 minutes. Deducting the temperature of the surrounding air, 63·5°, the increment of heat proved to be 72·5°, thus showing that by the intervention of the box, the differential temperature was increased threefold. It scarcely requires explanation that owing to the close proximity of the flame the air in the box becomes heated, imparting its heat to the thermometer, by convection; while the reflection of the heat rays against the sides and bottom of the polished box, imparts radiant heat to those parts of the bulb which are not exposed to the direct radiation of the flame.

In view of the foregoing explanation it will be evident that, in a properly conducted experiment, the temperatures recorded in Mr. Williams' table cannot be produced unless the thermometer be placed even nearer than 3 in. from the flame. But admitting that the recorded temperatures could be developed at a distance of 3 in., it will be found that the mistake to which Lord Rosse has called attention is fatal to Mr. Williams' deductions. Referring to Table B, constructed in accordance with

TABLE B.

No. of jet from Thermometer.	Energy Transmitted.	No. of jet from Thermometer.	Energy Transmitted.
1	2·77	10	0·90
2	2·37	11	0·82
3	2·04	12	0·75
4	1·77	13	0·69
5	1·56	14	0·64
6	1·38	15	0·59
7	1·23	16	0·55
8	1·11	17	0·51
9	1·00		

the theory pointed out by Lord Rosse in his letter to NATURE, it will be seen that each pair of jets so far from developing an equal amount of radiant energy, as indicated by Mr. Williams' table, they differ to a very great extent. For instance, while the two jets on each side of the centre develope respectively 1·11 and 0·90 (the energy transmitted by the central jet being represented by unity), the two outside jets develope respectively 2·77 and 0·51. Accordingly, the energy developed by the central pair will be 1·11 + 0·90 = 2·01, while the outside pair develope 2·77 + 0·51 = 3·28. Leaving out of sight the imperfections of the method adopted in making the observations, this great difference of the radiant energy transmitted to the thermometer by each pair of jets, is conclusive against the deduction concerning diathermacy of flame, which Mr. Williams has based on his published table of temperatures. J. ERICSSON

SCIENTIFIC SERIALS

THE *Archives des Sciences Physiques et Naturelles* contains a long and admirable article by Prof. Plantamour, on the meteorology of Geneva and the Great St. Bernard for 1871, a year of very exceptional weather at these places. In a series of carefully compiled tables, the various meteorological phenomena observed are compared in every possible way, and deserve the study of meteorologists. The second paper is an exceedingly interesting one from the work published by M. de Candolle, "Histoire des Sciences et des savants depuis deux Siècles," &c., containing the result of much acute and original research, on Transformations of Movement among Organised Beings. The other two principal papers are one by M. Ernest Favre, on the Geology of the Ralligstöcke on the banks of Lake Thun, and one by MM. de la Rive and Sarasin on the rotation under magnetic influence of the electric discharge in rarefied gases, and on the mechanical action which this discharge may exercise in its movement of rotation.

Transactions of the Wisconsin Academy of Science, Arts, and Letters, 1870-72. This academy was organised in 1870, "by a convention called by the Governor and more than one hundred other prominent citizens of the State," its general objects being "the material, intellectual, and social advancement of the State," as well as, or rather by means of the advancement of, science, literature, and the arts. This first volume of Transactions contains some specimens of the work already done by the Academy in its various departments, to which is prefixed an extremely interesting *résumé* of what has already been done by Wisconsin for science. This is followed by a long list of papers on various subjects read before the Academy since its formation. Of the scientific papers contained in the volume before us, Dr. Lapham contributes one "On the Classification of Plants;" Mr. J. G. Knapp "On the Coniferæ of the Rocky Mountains;" Prof. Irving on "The Age of the Quartzites, Schists, and Conglomerate of Sauk Co. Wisconsin;" Prof. Chamberlain a few suggestions, some of them original, as to a Basis for the Gradation of the Vertebrata; and Prof. Davies "On Potentials and their Application to Physical Science;" in which he attempts to give a *physical* interpretation to the potential function, and to illustrate it and its use by some simple examples. We hope the Academy will continue to produce as satisfactory work in the future as it has done since it commenced.

WE have received numbers 8, 9, 10, and 11 of the *Australian Mechanic and Journal of Science and Art* for August, September, October, and November, and highly creditable is the quality of the contents to its able editor, Mr. Ellery, Superintendent of Melbourne Observatory, and a hopeful sign of the intelligence and progress of the Australian people it is, that such a high-class scientific journal should have a paying circulation in so young a colony. Mr. Ellery himself is contributing a series of valuable and well illustrated articles on "How to make and how to use a Spectroscope," while another contributer, "Delta," concludes in the August number a series of seven papers on "Spectrum Analysis." The subjects treated of are very various, and mostly practical, but whatever the subject of an article may be, science and the application of scientific principles are never lost sight of. There is a series of articles on agriculture, in which the application of science to this department of industry is well illustrated; and in an article on "Science and Government," principally with reference to the supply of coal, the writer concludes thus:—"There is scarcely any subject within the range of material science, however trifling it may at first appear, that has not a direct and important interest for the whole community, and especially for those who hold the responsibility

of conducting the affairs and guarding the interests of the State." Would that all ministers would realise and act upon the great truth, so clearly and pithily expressed. Mr. Ellery contributes monthly a very valuable and interesting set of "Astronomical Notes," in which he gives all the details in a tabular form necessary to find out the positions, on the first of each month, of the planets, nebulæ, clusters, and double and other peculiar stars. We hope the journal will have all the success it well deserves.

SOCIETIES AND ACADEMIES

London

Royal Society, Jan. 30.—Prof. George Busk, vice-president, in the chair. The following communications were read:—"Note on the Origin of *Bacteria*, and on their Relation to the Process of Putrefaction." By Dr. H. Charlton Bastian, F.R.S.

In his now celebrated memoir of 1862, M. Pasteur asserted and claimed to have proved (1) that the putrefaction occurring in certain previously boiled fluids after exposure to the air was due to the contamination of the fluids by *Bacteria*, or their germs, which had before existed in the atmosphere; and (2) that all the organisms found in such fluids have been derived more or less immediately from the reproduction of germs which formerly existed in the atmosphere.

The results of a long series of experiments have convinced me that both these views are untenable.

In the first place, it can be easily shown that living *Bacteria*, or their germs, exist very sparingly in the atmosphere, and that solutions capable of putrefying are not commonly infected from this source.

It has now been very definitely ascertained that certain fluids exist which, after they have been boiled, are incapable of giving birth to *Bacteria*, although they continue to be quite suitable for the support and active multiplication of any such organisms as may have been purposely added to them. Amongst such fluids I may name that now commonly known as "Pasteur's solution," and also one which I have myself more commonly used, consisting of a simple aqueous solution of neutral ammonic tartrate and neutral sodic sulphate.* When portions of either of these fluids are boiled and poured into superheated flasks, they will continue quite clear for many days, or even for weeks—that is to say, although the short and rather narrow neck of the flask remains open the fluids will not become turbid, and no *Bacteria* are to be discovered when they are submitted to microscopical examination.

But in order to show that such fluids are still thoroughly favourable media for the multiplication of *Bacteria*, all that is necessary is to bring either of them into contact with a glass rod previously dipped into a fluid containing such organisms. In about thirty-six hours after this has been done (the temperature being about 80° F.), the fluid, which had hitherto remained clear, becomes quite turbid, and is found, on examination with the microscope, to be swarming with *Bacteria*.†

Facts of the same kind have also been shown by Dr. Burdon Sanderson‡ to hold good for portions of boiled "Pasteur's solution." Air was even drawn through such a fluid daily for a time, and yet it continued free from *Bacteria*.

Evidence of this kind has already been widely accepted as justifying the conclusion that living *Bacteria* or their germs are either wholly absent from, or, at most, only very sparingly distributed through the atmosphere. The danger of infection from the atmosphere having thus been got rid of and shown to be delusive, I am now able to bring forward other evidence tending to show that the first *Bacteria* which appear in many boiled infusions (when they subsequently undergo putrefactive changes) are evolved *de novo* in the fluids themselves. These experiments are moreover so simple, and may be so easily repeated, that the evidence which they are capable of supplying lies within the reach of all.

That boiling the experimental fluid destroys the life of any *Bacteria* or *Bacteria* germs pre-existing therein is now almost universally admitted. It may moreover be easily demonstrated. If a portion of "Pasteur's solution" be purposely infected with boiled *Bacteria* and subsequently boiled for two or three minutes, it will continue (if left in the same flask) clear for an indefinite period; whilst a similarly infected portion of the same fluid, not subsequently boiled, will rapidly become turbid. Precisely similar phenomena occur when we operate with the neutral fluid which I have previously mentioned; and yet M. Pasteur has ventured to assert that the germs of *Bacteria* are not destroyed in neutral or slightly alkaline fluids which have been merely raised to the boiling-point.*

Even M. Pasteur, however, admits that the germs of *Bacteria* and other allied organisms are killed in slightly acid fluids which have been boiled for a few minutes; so that there is a perfect unanimity of opinion (amongst those best qualified to judge) as to the destructive effects of a heat of 212° F. upon any *Bacteria* or *Bacteria* germs which such fluids may contain.

Taking such a fluid, therefore, in the form of a strong filtered infusion of turnip, we may place it after ebullition in a superheated flask with the assurance that it contains no living organisms. Having ascertained also by our previous experiments with the boiled saline fluids that there is no danger of infection by *Bacteria* from the atmosphere, we may leave the rather narrow mouth of the flask open, as we did in these experiments. But when this is done, the previously clear turnip infusion invariably becomes turbid in one or two days (the temperature being about 70° F.), owing to the presence of myriads of *Bacteria*.

Thus if we take two similar flasks, one of which contains a boiled "Pasteur's solution," and the other a boiled turnip infusion, and if we place them beneath the same bell-jar, it will be found that the first fluid remains clear and free from *Bacteria* for an indefinite period, whilst the second invariably becomes turbid in one or two days.

What is the explanation of these discordant results? We have a right to infer that all pre-existing life has been destroyed in each of the fluids; we have proved also that such fluids are not usually infected by *Bacteria* derived from the air—in this very case, in fact, the putrescible saline fluid remains pure, although the organic infusion standing by its side rapidly putrifies. We can only infer, therefore, that whilst the boiled saline solution is quite incapable of engendering *Bacteria*†, such organisms are able to arise *de novo* in the boiled organic infusion.

Although this inference may be legitimately drawn from such experiments as I have referred to, fortunately it is confirmed and strengthened by the labours of many investigators who have worked under the influence of much more stringent conditions, and in which closed vessels of various kinds have been employed.‡

Whilst we may therefore infer (1) that the putrefaction which occurs in many previously boiled fluids when exposed to the air is not due to a contamination by germs derived from the atmosphere, we have also the same right to conclude (2) that in many cases the first organisms which appear in such fluids have arisen *de novo*, rather than by any process of reproduction from pre-existing forms of life.

Admitting, therefore, that *Bacteria* are ferments capable of initiating putrefactive changes, I am a firm believer also in the existence of not-living ferments under the influence of which putrefactive changes may be initiated in certain fluids—changes which are almost invariably accompanied by a new birth of living particles capable of rapidly developing into *Bacteria*.

"On Just Intonation in Music; with a description of a new Instrument for the easy control of all Systems of Tuning other than the ordinary equal Temperament." By R. H. M. Bosanquet.

The object of this communication is to place the improved systems of tuning within the reach of ordinary musicians; for this purpose the theory and practice are reduced to their simplest form. A notation is described, adapted to use with ordinary written music, by which the notes to be performed are clearly distinguished. The design of a key-board is described, by which any system of tuning, except the ordinary equal temperament, can be controlled, if only the fifths of the system be all equal. The design is on a symmetrical principle, so that all passages and combinations of notes are performed with the same handling, in whatever key they occur. The theory of the construction of scales is then developed, and a diagram is given, from which the charac-

* In the proportion of 10 grains of the former and 3 of the latter to 1 ounce of distilled water.

teristics of any required system can be ascertained by inspection. An account is then given of the application of such systems to the new key-board, and particularly of a harmonium, which has been constructed, and contains at present the division of the octave into fifty-three equal intervals in a complete form. Rules for tuning are given. Finally, the application of the system of fifty-three to the violin is discussed.

Throughout the work of former labourers in the same field is reviewed; the obligations of the writer are due to Helmholtz, the late General T. Perronet Thompson, F.R.S., and others.

"On the Composition and Origin of the Waters of a Salt Spring in Huel Seton Mine, with a Chemical and Microscopical Examination of certain Rocks in its Vicinity." By J. Arthur Phillips.

After giving some tables, the author proceeds as follows:—A consideration of the various phenomena connected with the occurrence of this and other apparently similar springs, which have at different times been discovered in the district, would seem to lead to the inference that they all have some more or less direct communication with the sea, and that they are either the result of infiltration of sea-water through faults, or are true and independent sources which, before being tapped below the sea-level, had found their way to the ocean through faults or channels.

The following would appear, in the present state of our knowledge, a probable explanation of the origin of the Huel Seton spring. The cross-course is believed to extend through both granite and clay-slate to the sea. From the close contact of its surfaces, the presence of clay, and from other causes, this fault may be supposed not to be uniformly permeable by water, which can only follow a circuitous passage. In this way it penetrates to depths where reactions take place, which, although not entirely in accordance with the results of daily experience in our laboratories, can, after the investigations of M. Daubrée, M. de Sénarmont, and others, be readily understood. By the action of *sea-water* on *silicates of calcium*, *silicates of sodium* and *chloride of calcium* may be produced. The *sulphate of sodium* of the sea-water will be decomposed by this *chloride of calcium*, with the production of *sulphate of calcium* and *chloride of sodium*. The decomposition of clayey matter by *common salt* may produce *chloride of aluminium* and *silicates of sodium*, while the *magnesium* of the chloride of magnesium may be replaced by *calcium*; lastly, a portion of the *potassium* in the sea-water appears to have been replaced by the *lithium* of the granite.

Royal Geographical Society, Jan. 27.—Major-General Sir H. C. Rawlinson, K.C.B., president, in the chair.—"Journey from Bunder Abbas to Meshed, by Seistan," by Sir Frederick Goldsmid. The object of the author's journey was to carry into effect a settlement of the frontiers of Seistan, with which he had been entrusted. He left Bunder Abbas for the interior, with his party, on December 23, 1871, travelling in an E.N.E. direction first towards Bam. Beyond Bam and Azizabad, the country was fertile and well cultivated; this afterwards ceases, and near Fahraj the central desert begins. Beyond this, to the west, is another tract of mountainous country, bounding the fertile district of Seistan. The Hamun Lake was found dry, except pools of water at the mouths of the rivers, and the party crossed its southern part, where the bed was perfectly dry. Its limits are, however, well-marked by belts of reeds. The waters of the Helmund near and in the Delta had been led off by irrigation canals. The area of Seistan Proper was estimated at 947 square miles, and the population at 35,000. Majors St. John and Lovett, R.E, the surveyors attached to the party, had superintended the execution of a new wall-map of Persia, which was exhibited, and which gave quite a new character to the geography of many parts of Persia. The two great central areas of desert (1,500 to 3,000 feet above the sea-level) were clearly shown, and the snowy-ranges running in a north-west and south-east direction, nearly parallel to the Persian Gulf, well defined. One of these ranges rises to a height of more than 17,000 feet.—"On the Comparative Geography and Ethnology of Seistan," by the President. The country physically is dependent entirely on the River Helmund; and it is probable the earliest Aryan colonists drew off the whole of the water for irrigation, for in the earliest Geographical List, that contained in the "Vendidad," the country was called, not from the lake, but from the river. None of the sites of the cities and places named in ancient history could be identified with certainty. Seistan formed the most southerly province of the ancient Aryan country of Iran.

*MODERN APPLICATIONS OF THE DOCTRINE OF NATURAL SELECTION**

NOTWITHSTANDING the objections which are still made to the theory of Natural Selection on the ground that it is either a pure hypothesis not founded on any demonstrable facts, or a mere truism which can lead to no useful results, we find it year by year sinking deeper into the minds of thinking men, and applied, more and more frequently, to elucidate problems of the highest importance. In the works now before us we have this application made by two eminent writers, one a politician, the other a naturalist, as a means of working out so much of the complex problem of human progress as more especially interests them.

Mr. Bagehot takes for granted that early progress of man which resulted in his separation into strongly marked races, in his acquisition of language, and of the rudiments of those moral and intellectual faculties which all men possess; and his object is to work out the steps by which he advanced to the condition in which the dawn of history finds him,—aggregated into distinct societies known as tribes or nations, subject to various forms of government, influenced by various beliefs and prejudices, and the slave of habits and customs which often seem to us not only absurd and useless, but even positively injurious. Now every one of these beliefs or customs, or these aggregations of men into groups having some common characteristics, must have been useful at the time they originated; and a great feature of Mr. Bagehot's little book is his showing how even the most unpromising of these, as we now regard them, might have been a positive step in advance when they first appeared. His main idea is, that what was wanted in those early times was some means of combining men in societies, whether by the action of some common belief or common danger, or by the power of some ruler or tyrant. The mere fact of obedience to a ruler was at first much more important than what was done by means of the obedience. So, any superstition or any custom, even if it originated in the grossest delusion, and produced positively bad results, might yet, by forming a bond of union more perfect than any other then existing, give the primitive tribe subject to it such a relative advantage over the disconnected families around them, as to lead to their increase and permanent survival in the struggle for existence. In those early days war was perhaps the most powerful means of forcing men to combined action, and might therefore have been necessary for the ultimate development of civilisation. Freedom of opinion was then a positive evil, for it would lead to independent action, the very thing it was most essential to get rid of. In early times isolation was an advantage, in order that these incipient societies might not be broken up by intermixture, and it was only after a large number of such little groups, each with its own idiosyncrasics, habits, and beliefs, had been formed, that it became advantageous for them to meet to intermingle or to struggle together, and the stronger to drive out or exterminate the weaker. Out of the great number of petty tribes thus formed, only a few had the qualities which led to a further advancement. The rest were either exterminated or driven out into remote and inaccessible or inhospitable districts, and some of those are the "savages" which still exist on the earth, serving as a measure of the vast progress of the human race. Yet even these never show us the condition of the primitive man; they are men who advanced up to a certain point and then became stationary:—

"Their progress was arrested at various points; but nowhere, not even in the hill tribes of India, not even in the Andaman Islands, not even in the savages of Terra del Fuego, do we find men who have not got some way. They have made their little progress in a hundred different ways; they have framed with infinite assiduity a hundred curious habits; they have, so to say, *screwed* themselves into the uncomfortable corners of a complex life, which is odd and dreary, but yet is possible. And the corners are never the same in any two parts of the world. Our record begins with a thousand unchanging edifices, but it shows traces of previous building. In historic times there has been but little progress, in prehistoric times there must have been much."

Again our author shows how valuable must have been the institution of caste in a certain stage of progress. It established the division of labour, led to great perfection in many arts, and rendered government easy. Caste nations would at first have a great advantage over non-caste nations, would conquer them and increase at their expense. But a caste nation at last becomes stationary; for a habit of action and a type of mind which it can with difficulty get rid of is established in each caste. When this is the case, non-caste nations soon catch them up, and rapidly leave them far behind.

This outline will give some idea of the way in which Mr. Bagehot discusses an immense variety of topics connected with the progress of societies and nations and the development of their distinctive peculiarities. The book is somewhat discursive and sketchy, and it contains many statements and ideas of doubtful accuracy, but it shows an abundance of ingenious and original thought. Many will demur to the view that mere accident and imitation have been the origin of marked national peculiarities; such as those which distinguish the German, Irish, French, English, and Yankees: "The accident of some predominant person possessing certain peculiarities set the fashion, and it has been imitated to this day"; and again, "Great models for good or evil sometimes appear among men who follow them either to improvement or degradation." This is said to be one of the chief agents in "nation-making," but a much better one seems to be the affinity of like for like, which brings and keeps together those of like morals or religion or social habits; but both are probably far inferior to the long-continued action of external nature on the organism, not merely as it acts in the country now inhabited by the particular nation, but by its action during remote ages and throughout all the migrations and intermixtures that our ancestors have ever undergone. We also find many broad statements as to the low state of morality and of intellect in all prehistoric men, which facts hardly warrant, but this is too wide a question to be entered

* "Physics and Politics; or, Thoughts on the Application of the Principles of 'Natural Selection' and 'Inheritance' to Political Society." By Walter Bagehot. (King and Co., 1872.)

"Histoire des Sciences et des Savants depuis deux Siècles suivie d'autres études sur les Sujets Scientifiques en particulier sur la Sélection dans l'Espèce Humaine." Par Alphouse de Candolle. (Genève: H. Georg, 1873.)

upon here. In the concluding chapter, "The Age of Discussion," there are some excellent remarks on the restlessness and desire for immediate action which civilised men inherit from their savage ancestors, and how much it has hindered true progress; and the following passage, with which we will conclude the notice of Mr. Bagehot's book, might do much good if by means of any skilful surgical operation it could be firmly fixed in the minds of our legislators and of the public:—

"If it had not been for quiet people, who sat still and studied the sections of the cone, if other people had not sat still and worked out the doctrine of chances, the most 'dreamy moonshine,' as the purely practical mind would consider, of all human pursuits; if 'idle star-gazers' had not watched long and carefully the motions of the heavenly bodies, our modern astronomy would have been impossible; and without astronomy, 'our ships, our colonies, our seamen,' all that makes modern life, could not have existed. Ages of quiet, sedentary, thinking people were required before that noisy existence began, and without those pale preliminary students, it never could have been brought into being. And nine-tenths of modern science is, in this respect, the same; it is the produce of men whom their contemporaries thought dreamers—who were laughed at for caring for what did not concern them—who, as the proverb went, 'walked into a well from looking at the stars'—who were believed to be useless, if anyone could be such. And the conclusion is plain, that if there had been more such people, if the world had not laughed at those there were, if rather it had encouraged them, there would have been a great accumulation of proved science ages before there was. It was the irritable activity, the 'wish to be doing something,' that prevented it. Most men inherited a nature too eager and too restless to find out things; and even worse—with their idle clamour they 'disturbed the brooding hen,' they would not let those be quiet who wished to be so, and out of whose calm thought much good might have come forth. If we consider how much good science has done, and how much it is doing for mankind, and if the over-activity of men is proved to be the cause why science came so late into the world, and is so small and scanty still, that will convince most people that our over-activity is a very great evil."

In the second work, of which we have given the title, the veteran botanist, Alphonse de Candolle, sets forth his ideas on many subjects not immediately connected with the science in which he is so great an authority. The most important, though not the longest, essay in the volume is that on "Selection in the Human Race," in which he arrives at some results which differ considerably from those of previous writers. In a section on "Selection in Human Societies or Nations," we find a somewhat novel generalisation as to the progress and decay of nations. Beginning with small independent states, we see a gradual fusion of these into larger and larger nations, sometimes voluntary, sometimes by conquest, but the fusion always goes on, and tends to become more and more complete, till we have enormous aggregations of people under one government, in which local institutions gradually disappear, and result in an almost complete political and social uniformity. Then commences decay; for the individual is so small a unit, and so powerless to influence the Government, that the mass of men resign themselves to passive obedience. There is then no longer any force to resist internal or external enemies, and by means of one or the other the "vast fabric" is dismembered, or falls in ruins. The Roman Empire, and the Spanish Possessions in America, are examples of this process in the past; the Russian Empire and our Indian Possessions will inevitably follow the same order of events in a not very distant future.

Although M. de Candolle is a firm believer in Natural Selection, he takes great pains to show how very irregular and uncertain it is in its effects. The constant struggles and wars among savages, for example, might be supposed to lead to so rigid a selection, that all would be nearly equally strong and powerful; and the fact that some savages are so weak and incapable as they are, shows, he thinks, that the action of natural selection has been checked by various incidental causes. He omits to notice, however, that the struggle between man and the lower animals was at first the severest, and probably had a considerable influence in determining race-characters. It may be something more than accidental coincidence that the most powerful of all savages—the negroes—inhabit a country where dangerous wild beasts most abound; while the weakest of all—the Australians—do not come into contact with a single wild animal of which they need be afraid.

Selection among barbarous nations will often favour cunning, lying, and baseness; vice will gain the advantage, and nothing good will be selected but physical beauty. Civilisation is defined by the preponderance of three facts—the restriction of the use of force to legitimate defence and the repression of illegitimate violence, speciality of professions and of functions, and individual liberty of opinion and action under the general restriction of not injuring others. By the application of the above tests we can determine the comparative civilisation of nations; but too much civilisation is often a great danger, for it inevitably leads to such a softening of manners, such a hatred of bloodshed, cruelty, and injustice as to expose a nation to conquest by its more warlike and less scrupulous neighbours. Progress in civilisation must necessarily be very slow, and to be permanent must pervade all classes and all the surrounding nations; and it is because past civilisations have been too partial that there have been so many relapses into comparative barbarism. All this is carefully worked out, and is well worthy of attention.

In the last section, on the probable future of the human race, we have some remarkable speculations, very different from the somewhat utopian views held by most evolutionists, but founded nevertheless on certain very practical considerations. In the next few hundred or a thousand years the chief alterations will be the extinction of all the less dominant races, and the partition of the world among the three great persistent types, the whites, blacks, and Chinese, each of which will have occupied those portions of the globe for which they are best adapted. But, taking a more extended glance into the future, of 50,000 or 100,000 years hence, and supposing that no cosmical changes occur to destroy, wholly or partially, the human race, there are certain well-ascertained facts on which to found a notion of what must by that time have occurred. In the first place, all the coal and all the metals available will then have been exhausted, and even if men succeed in finding other sources of heat,

and are able to extract the metals thinly diffused through the soil, yet these products must become far dearer and less available for general use than now. Railroads and steamships, and everything that depends upon the possession of large quantities of cheap metals, will then be impossible, and sedentary agricultural populations in warm and fertile regions will be the best off. Population will have lingered longest around the greatest masses of coal and iron, but will finally become most densely aggregated within the tropics. But another and more serious change is going on, which will result in the gradual diminution and deterioration of the terrestrial surface. Assuming the undoubted fact that all our existing land is wearing away and being carried into the sea, but by a strange oversight, leaving out altogether the counteracting internal forces, which for countless ages past seem always to have raised ample tracts above the sea as fast as subaërial denudation has lowered them, it is argued that, even if all the land does not disappear and so man become finally extinct, yet the land will become less varied and will consist chiefly of a few flat and parched-up plains, and volcanic or coralline islands. Population will by this time necessarily have much diminished, but it is thought that an intelligent and persevering race may even then prosper. "They will enjoy the happiness which results from a peaceable existence, for, without metals or combustibles it will be difficult to form fleets to rule the seas or great armies to ravage the land;" and the conclusion is that, "such are the probabilities according to the actual course of things." Now, although we cannot admit this to be a probability on the grounds stated by M. de Candolle, it does seem a probability, at some more distant epoch, on other grounds. The great depths of the oceans extend over wide areas, whereas the great heights of the land are only narrow ridges and peaks; hence it has been calculated that the mean height of the land is only 1,000 feet, while the mean depth of the sea is about 15,000 feet. But the sea is 2½ times as extensive as the land, so that the bulk or mass of the land above the sea level will be only about one thirty-seventh of the mass of the ocean. Now, does not this small proportion of bulk of land to water render it highly probable that the forces of elevation and depression should sometimes cause the total or almost total submersion of the land? Of such an epoch no geological record could be left because there could be no strata formed, except from the *débris* of coral islands, and such a period of destruction of the greater part of terrestrial life may have repeatedly occurred between the period when the several Primary or Secondary formations were deposited. At all events, with such a proportion of land and sea surface as now exists, with such a small bulk of land above the enormous bulk of water, and with no known cause why the dry land rather than the sea-bottom should be constantly elevated, we must admit it to be almost certain that great fluctuations of the area of the land must occur, and that, while those fluctuations could not very considerably increase the area of the land they might immensely diminish it. There is here, therefore, a cause for the possible depopulation of the earth likely to occur much sooner than any cosmical catastrophe.

The largest and most elaborate essay in the volume is that on the "History of the Sciences and of Scientific Men for the last two Centuries." In this the author endeavours to arrive at certain conclusions as to the progress of science under different conditions and in different countries, the influence of political institutions and of heredity, and various other phenomena, by a method which is novel and ingenious. He takes account only of the men honoured as foreign associates or members by the three great European Scientific bodies, the Royal Society of London and the Paris and Berlin Academies. By this means he avoids all personal bias, and secures, on the whole, impartiality. The tables drawn out by this method are examined in every possible way, and the results worked out in the greatest detail. The main conclusion arrived at is the determination of a series of eighteen causes favourable to the progress of science; and it is shown that a large proportion of these are present in a considerable degree in countries where science flourishes, while they are almost wholly absent in barbarous or semi-civilised countries where science does not exist.

Another interesting essay is that on the importance for science of a dominant language, and it contains some very curious facts as to the way in which the English language is spreading on the Continent. M. de Candolle believes that in less than two centuries English will be the dominant language, and will be almost exclusively used in scientific works.

There are also short but very interesting essays on methods of teaching drawing and developing the observing powers of children, on statistics and free will, and on a few other subjects of less importance, all of which are treated in a thoughtful manner, and illustrate one of the views on which much stress is laid in this work, viz., that the mental faculties which render a man great in any science are not special, but would enable him to attain equal eminence in many other branches of science or in any profession al or political career.

ALFRED R. WALLACE

HÄCKEL ON SPONGES

Die Kalkschwämme. Eine Monographie. Von Ernst Häckel. 2 vols., with an additional vol. of 60 lithographic plates. (Berlin, 1872.)

THIS splendid contribution to the knowledge of the sub-class of Calcareous Sponges is worthy of the high reputation of Prof. Häckel. In the preface he speaks of it as one of the many results of the stimulus given to zoology by the Darwinian Theory; and the list of those who have contributed the materials on which this monograph is based is honourable alike to the author and to the friendly helpers from our own and every other civilised country. It includes the names of Agassiz from the United States, Allman from Edinburgh, Percival Wright from Dublin, Barboza du Bocage from Lisbon, Lacaze Duthiers from Paris, the lamented Claparède from Geneva, Eschmark and Sars from Christiania, Steenstrup from Copenhagen, and Lieberkühn, Peters, Oscar Schmidt, Semper, von Siebold and many others from Germany. In addition to this, the author has himself collected sponges in Heligoland, Nice, Naples, Messina, the Canaries and Mogador, Algesiras, Bergen, and the neighbouring Norwegian coast, and lastly in the Adriatic Sea.

With this admirable material, and, what is no less important, with the philosophical spirit which a mere specialist always lacks, it is no wonder that a work of the first importance has been produced.

The first chapter gives an appreciative account of the admirable labours of Prof. Grant, and of the subsequent contributions to the subject by Johnston, Bowerbank, Lieberkühn, Carter, Oscar Schmidt, and Kölliker. The defects of Mr. Bowerbank's "Monograph of British Sponges" are clearly pointed out, but its great merits receive equally cordial recognition, while the criticism passed on Dr. Gray's "Classification" is as just as it is severe.

After a description of the methods of examination, the author proceeds to give a detailed account of the anatomy and natural history of the calcareous sponges, and this occupies the greater part of the first volume. The second is devoted to a detailed description of the whole group in systematic order, with diagnosis of species and ample synonomy. The plates in the third volume, drawn by Prof. Häckel with the camera lucida, are admirably exact, though artistic effect is sometimes sacrificed to a somewhat diagrammatic clearness. They remind one of the excellent illustrations of Bronn's "Thierreich."

The class of sponges is divided into *Fibrospongiæ*, including most of Grant's and Bowerbank's siliceous and ceratose genera, *Myxospongiæ*, represented by *Halisarca* and *Calcispongiæ vel Granticæ*. This third class contains three families, Ascones (Leucosolenia Bowerbank), Leucones (Leuconia Bowerbank), and Sycones (Grantia Bowerbank), represented by *Ascetta, Leucetta* and *Sycetta* respectively. The genera are chiefly characterised by their spicula.

The author agrees with Oscar Schmidt in deducing all known sponges from a single primitive form (Archispongia, Protospongia), which he supposed to have resembled *Halisarca* more than any other existing genus. He regards the class as very distinct from the Protozoa, and most nearly related to the Cœlenterata, a view with which English readers are familiar from Mr. E. R. Lankester's interesting paper on Zoological Affinities of Sponges in the Annals and Magazine of Natural History (vol. vi. 1870). Indeed it was the position taken by Leuchart himself in 1854, seven years after the sub kingdom of Cœlenterata had been established by himself and Frey. If we admit that each sponge-pyramid is not a colony of Protozoa, but a multicellular organism, its likeness to a polyp is very striking: the chief differences are the absence of tentacles and of thread-cells. The latter structures, however, have, we believe, been detected in some Mediterranean sponges since the publication of Prof. Häckel's work.

Comparing the "Stammbaum" given at the end of the first volume with that in the third edition of the "Schöpfungsgeschichte" (1872), published five months earlier, we find that the author now makes all sponges descend through "Archispongia," and "Protascus" from an equally hypothetical "Gastræa," while the Cœlenterata diverge from Protascus as Archydra. This makes the affinity less close between Myxospongiæ on the one hand, and between Calcispongiæ and Coralligena on the other. The modification brings the Stammbaum nearer to the classifications actually used by other zoologists and is so far an advantage.

With regard to nomenclature, Prof. Häckel defends the proposal which he made in 1869 to revive the old name of Zoophyta (used by our countryman Wotton in 1552) in order to include sponges (or Porifera) and Cœlenterata (or, as he prefers to call them, Acalephæ). Admitting the justice of the classification, there seems no sufficient justification for the change of names. 1. Priority belongs to the name given by those who first establish true affinities, and not to vague and fanciful names given two hundred years before Linnæus. 2. To say "Zoophyta" is no worse a name to revive than "Vermes" is sufficiently to condemn it. 3. Whether the cavity in a sea-anemone is all stomach or partly perivisceral may admit of dispute, but "Cœlenterata" only affirms that the animal is hollow; and if the term suggests either interpretation, it rather lends itself to Prof. Häckel's. 4. If another word must be invented to apply to Anthozoa (or "Coralla") and Hydrozoa (or "Hydromedusæ") in common, Huxley's "Nematophora," suggested in 1851, is just as good as "Acalephæ," which was used in a more restricted sense by Cuvier. But it is not impossible that before long neither term will be properly exclusive of sponges.

These perpetual changes of names and invention of fresh ones to fit kinsfolk of every shade of propinquity and even avowedly mythological ancestors, is a real drawback to the value of such excellent works as this, and is almost as bad as the endless nomenclature of the species-mongers with whom Prof. Häckel is so justly indignant. However the new wine is still working, and we may say of even "endless genealogies"—

> "Doch sind wir auch mit diesen nicht gefährdet,
> In wenig Jahren wird es anders sein:
> Wenn sich der Most auch ganz absurd geberdet,
> Es gibt zuletzt doch noch 'nen Wein."

And this book will remain an important contribution to philosophical zoology, no less than to the special history of the group to which it is devoted. P. S.

OUR BOOK SHELF

Grotesque Animals. Invented, Drawn, and Described by E. W. Cooke, R.A., F.R.S., F.G.S., F.Z.S., &c. (London: Longmans, Green, and Co., 1872.)

MR. E. W. COOKE possesses so high a reputation, not only as one of the leading artists of the day, but also as a man eminently devoted to science, as evidenced by the fact of his having attained the double distinction of Royal Academician and Fellow of the Royal Society, that anything proceeding from his pencil cannot fail to be worthy of notice, and we have accordingly looked through this quaint collection of facsimile drawings with very great interest. Mr. Cooke states, in his preface, that he commenced this series of "grotesque combinations," to which he also assigns the euphonious title of "Entwickelungsgeschicte" (history of development), while seeking rest and relief on the Somersetshire Coast after the dissipation attendant upon the meeting of the British Association at Manchester, in 1864, and that the idea of publication was forced upon him by friends who wished to have copies of the drawings. We are not surprised at his numerous friends and admirers desiring that these results of his holiday recreations should be given to the world; for, apart from the merits of the drawings in an artistic point of view, containing, as they do, powerful delineations of animal forms, they exhibit a singular and

amusing fertility of imagination, the *disjecta membra* of birds, beasts, and fishes, being worked up together in a variety of fantastic forms which it would puzzle Mr. Darwin or Professor Owen to classify. The plates are accompanied by short descriptions, also by Mr. Cooke, and intended, he says, "as a key to aid the unintiated in animal lore." We give our readers the following descriptions as a sample:—"Plate v. No. 1. An odd fish—Platax—with dress of a bivalve shell, *Pecten Gibbosus*. The feet of a sprat-loon, *Colymbus Stellatus*, and tail of Beroe. No. 2. *Encrinus entrocha*, a Lily-encrinite, wears the head-dress of a porpita, one of the Acalephæ. Her dress being of Flustra, her right arm is a Pentelasmis, her left a species of Serpula. No. 3. This pig-faced lady, whose body is '*Parasmilia centralis*,' has wings of *Avicula cygnipes* (both species from the chalk), and limbs of a bird (species unknown). . . Plate x. No. 1. This scaly creature, capped by Cephalaspis, has the feet of a Brazilian porcupine, the heterocercal tail of a Palæozoic fish, and the lower jaw and tusks of Dinotherium wherewith to scratch himself. . . Plate xiii. No. 3. This ancient spinster, truly Palæozoic, has the triturating teeth of a fish, *Cestracion Philipi*; her cap is an Argonauta, her body that of the Port Jackson shark, her fan (Spanish, of course) a Renilla. *Isis hippuris* furnishes her arms . . . Plate xviii. No. 1. This hollow character, formed of the lower jaw of the hippopotamus, has very diverse arms, the right being an Ancyloceras, the left *Hamites attenuatus*. His head-gear is well got up with hide, horns, and the beak of a spoonbill! . . . Plate xx. No. 1, thanks to Monte Bolca and its elevated strata of *dried* fish, we have *Semiophorus velifer* (a fish of the Eocene.) With Scutes on his neck, and the claws of a lion, he walks his chalks; an upper cretaceous shell, *Plagiostoma spinosum*, defends his body." Many of the plates remind us of the gambols of the crustaceæ and other marine animals in *Babil and Bijou*, and we have no doubt that Mr. Boucicault, in his next attempt to "improve the British Drama," will find in this volume an endless variety of suggestions for humorous stage effects. We must not omit to mention the admirable manner in which the drawings have been reproduced by Mr. Sawyer of the Autotype Fine Art Company, the plates being exact facsimiles of the drawings. We anticipate an extensive circulation for this beautifully-executed and entertaining work. G. I. F. C.

Abstract of the Reports of the Surveys and other Geographical Operations in India for 1870-71.

We learn from these reports that during the season of 1870-71, the Great Trigonometrical Survey has been proceeded with on six series, and the complete work is represented by 11,203 square miles of principal, and 10,076 of secondary triangulation. The total area surveyed up to 1871 by the Topographical Surveys which do not include the Topographical work of the Trigonometrical Survey, is 665,909 square miles, three times the area of France. The Geological Survey has been going on more briskly than in previous years, and the Geological Surveyors are gradually building up the materials which will enable a geological map of India to be prepared. The tidal observations, from which much was expected, and for which gauges were made and sent out to India more than two years ago, were not gone on with on account of the financial difficulties of the Indian government. The government has finally adopted Mr. Hunter's plan for the spelling of Indian names; it is as near an approach to what is known as the "scientific system," as the public in the present state of education are able to endure. The "scientific system" consists in scrupulously rendering letter for letter, without any particular care to preserve the pronunciation. Uniformity in the spelling of geographical names is a great matter, no matter on what principle it may be based.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Inherited Instinct

The following letter seems to me so valuable, and the accuracy of the statements vouched for by so high an authority, that I have obtained permission from Dr. Huggins to send it for publication. No one who has attended to animals either in a state of nature or domestication will doubt that many special fears, tastes, &c., which must have been acquired at a remote period, are now strictly inherited. This has been clearly proved to be the case by Mr. Spalding with chickens and turkeys just born, in his admirable article recently published in *Macmillan's Magazine*. It is probable that most inherited or instinctive feelings were originally acquired by slow degrees through habit and the experience of their utility; for instance the fear of man, which as I showed many years ago, is gained very slowly by birds on oceanic islands. It is, however, almost certain that many of the most wonderful instincts have been acquired independently of habit, through the preservation of useful variations of pre-existing instincts. Other instincts may have arisen suddenly in an individual and then been transmitted to its offspring, independently both of selection and serviceable experience, though subsequently strengthened by habit. The tumbler-pigeon is a case in point, for no one would have thought of teaching a pigeon to turn head over heels in the air; and until some bird exhibited a tendency in this direction, there could have been no selection. In the following case we see a specialised feeling of antipathy transmitted through three generations of dogs, as well as to some collateral members of the same family, and which must have been acquired within a very recent period. Unfortunately it is not known how the feeling first arose in the grandfather of Dr. Huggins's dog. We may suspect that it was due to some ill-treatment; but it may have originated without any assignable cause, as with certain animals in the Zoological Gardens, which, as I am assured by Mr. Bartlett, have taken a strong hatred to him and others without any provocation. As far as it can be ascertained, the great-grandfather of Dr. Huggins's dog did not evince the feeling of antipathy, described in the following letter.

Charles Darwin

"I wish to communicate to you a curious case of an inherited mental peculiarity. I possess an English mastiff, by name Kepler, a son of the celebrated Turk out of Venus. I brought the dog, when six weeks old, from the stable in which he was born. The first time I took him out he started back in alarm at the first butcher's shop he had ever seen. I soon found he had a violent antipathy to butchers and butchers' shops. When six months old, a servant took him with her on an errand. At a short distance before coming to the house, she had to pass a butcher's shop; the dog threw himself down (being led with a string), and neither coaxing nor threats would make him pass the shop. The dog was too heavy to be carried; and as a crowd collected, the servant had to return with the dog more than a mile, and then go without him. This occurred about two years ago. The antipathy still continues, but the dog will pass nearer to a shop than he formerly would. About two months ago, in a little book on dogs published by Dean, I discovered that the same strange antipathy is shown by the father, Turk. I then wrote to Mr. Nichols, the former owner of Turk, to ask him for any information he might have on the point. He replied—'I can say that the same antipathy exists in King, the sire of Turk, in Turk, in Punch (son of Turk, out of Meg) and in Paris (son of Turk, out of Juno). Paris has the greatest antipathy, as he would hardly go into a street where a butcher's shop is, and would run away after passing

it. When a cart with a butcher's man came into the place where the dogs were kept, although they could not see him, they all were ready to break their chains. A master-butcher, dressed privately, called one evening on Paris's master to see the dog. He had hardly entered the house before the dog (though shut in) was so much excited that he had to be put into a shed, and the butcher was forced to leave without seeing the dog. The same dog at Hastings made a spring at a gentleman who came into the hotel. The owner caught the dog and apologised, and said he never knew him to do so before, except when a butcher came to his house. The gentleman at once said that was his business. So you see that they inherit these antipathies, and show a great deal of breed.' "WILLIAM HUGGINS"

The unreasonable

MY attention has directed itself to a letter by Dr. Ingleby in your last number, containing two curious but inconsistent misrepresentations of my words, and therein something that, if the writer were not Dr. Ingleby, might be called an instructive instance of cynophatnism or doggimangerness—the behaviour of one who will neither understand a thing himself, nor allow other folk to understand it. As, however, the writer is Dr. Ingleby, I feel sure that a less cursory contemplation of the matter will modify his views.

The following doctrines are in the *Kritik* :—

1. At the basis of the natural order is a transcendental object.

"Das *transcendentale Object*, welches den aüsseren Erscheinungen, ingleichen das, was der inneren Anschauung zum Grunde liegt, ist weder Materie, noch ein denkendes Wesen an sich selbst, sondern ein uns unbekannter Grund der Erscheinungen, die den empirischen Begriff von der ersten sowohl als zweiten art an die Hand geben." (IVth Paralogism, of Ideality ; *First Edition.*)

2. The transcendental object is *unreasonable*, or evades the processes of human thought.

(*a*) Of the sensibility :—

"Die nichtsinnliche . . . Ursache dieser Vorstellungen ist uns gänzlich unbekannt, und diese können wir daher nicht als Object anschauen." . . . (VIth section of Antithetic.)

(*b*) Of the understanding :—

"Unser Verstand . . Dinge an sich selbst (nicht als Erscheinungen betrachtet) *Noumena* nennt. Aber er setzt sich auch sofort selbst Grenzen, sie durch keine Kategorien zu erkennen, mithin sie nur unter dem Namen eines unbekannten Etwas zu denken." (Ground of distinction between Phenomena and Noumena.)

3. The doctrine of the contradictions is one means by which we know this.

"Mann kann aber auch umgekehrt aus dieser Antinomie . . . die transcendentale Idealität der Erscheinungen . . . indirect . . . beweisen," &c. (VIIth section of Antithetic.)

The Kantian theory had two legs to stand upon; one the alleged necessity of mathematical axioms, the other these alleged necessary contradictions in our ideas of the natural order. How completely the first has been amputated I hope to have shortly an opportunity of showing in a course of lectures at the Royal Institution. The doctrine, that we may infer the existence of an unknowable from supposed contradictions in the knowable, "has been developed and extended by the great successors of Kant;" and when in "a later form" these contradictions were set forth from an ultimately empirical standpoint (*not* that of Hamilton, but of Spencer, as stated in my note) the doctrine became fit for notice in a scientific lecture. Only the contradictions themselves, however, could be criticised, and not the step from them to the existence of the unknowable, or the unknowability of the existent. And Kant's name could only be mentioned as the historical starting-point of the doctrine; whose importance for the empiricist is mainly due to the modifications it has undergone since his time.

If Dr. Ingleby will kindly look at my lecture (*Macmillan's Magazine*, October 1872) again, he will see that I have attributed to Kant no more than the above-quoted doctrines; that I never pretended to expound Kant's form of them, or their relation to the rest of his system; and that I never said nor accused anybody of saying either that the antithetic was unreasonable, or that any natural order of thought or things was unreasonable. In regard to the other misrepresentations he speaks of, I shall be very glad indeed to be told of them, and to be set right, provided only they exist in my words, and not in the exuberant imagination of my critic.

London, Feb. 9 W. K. CLIFFORD

P.S.—There is an important error in p. 508 of the lecture in question. The surface-tension of camphor and water is *less* than that of water, not *greater*, as there stated. The general argument depends only on there being a difference.

Prof. Clifford on Curved Space

THE friend, who (as I stated in my letter in NATURE, Feb. 6) called my attention to Prof. Clifford's address in *Macmillan's Magazine* for October last, asked me certain questions respecting curved space, which I was quite unable to answer: and another friend, occupying the foremost place among English philosophers, has since communicated to me the great discomfort which Prof. Clifford's views had occasioned him, and suggested that I should comment upon them in NATURE. I am not sure that what I have to say will prove to be helpful either to my discomforted friend, or to truth : yet the doctrine of curved space is so extraordinary in itself, and so momentous in its consequences, if it be true, that it is a fair subject for sceptical scrutiny. Moreover, I do not conceive that in commenting upon it I am going *ultra crepidam* ; for the nature of space is not a subject on which the mathematician can claim a monopoly. *In limine* allow me to express my regret that Prof. Clifford should have selected such a topic for the entertainment of a popular audience. It is quite incredible that any of his hearers could have apprehended his meaning. There was assuredly no need for the lecturer to have cast a glamour on their mental eye by the invocation of those awful names, Lobatchewsky and Gauss, Riemann and Helmholtz.

The principle, in exemplification of which Prof. Clifford expounded the doctrine in question, was this : that a law can be only provisionally universal (*i.e.* as "we find that it pays us to assume it"), but that it is theoretically universal, or true of all cases whatever, "is what we do not know of any law at all" p. 504. I fancy he would not include numerical formulæ under the term "law :" else arithmetic and algebra would afford an infinity of examples of such a law. Be that as it may, he does not select an example from either of those sciences, but from Euclidian geometry. He takes the proposition established by Euclid, that in any plane triangle the three angles added together are equal to two right angles. This he asserts we do not know as a universal truth. I now quote his own words: "Now suppose that three points are taken in space, distant from one another as far as the sun is from α Centauri, and that the shortest distances between these points are drawn so as to form a triangle ; and suppose the angles of this triangle to be very accurately measured and added together ; this can at present be done so accurately that the error shall certainly be less than one minute. . . . Then I do not know that this sum [? apart from the question of error] would differ at all from two right angles; but also I do not know that the difference would be less than 10°." If, then, after a sufficient number of observations it were found that the deviation were greater than the assigned limit of error (less than one minute), it would follow that the Euclidian law is not universal, and that for triangles of such dimensions it is not true. The conclusion would be, then, that our Tridimensional space is not a homaloid. We need not run our heads against the ghost of a fourth dimension ; for the refinements of the geometer enable him to investigate a curved tridimensional space, just as he investigates a homaloidal tridimensional space. But all the same, it is absurd to attempt the interpretation of the results without supposing that fourth dimension as the *conditio sine quâ non.*

Now we will suppose that the triangle in question has been surveyed, and that the sum of its three angles have been found to deviate from π far beyond the assigned limit of error: what have we really got thereby? The triangle, says Prof. Clifford, is formed by drawing "lines of shortest distance" between the three points in space. Is observation through a telescope drawing such a line? Be it so, for the sake of argument. Then, if the conclusion to be drawn is that space is curved, I ask does it or does it not follow that the sides of the triangle are themselves curved? Observe that if those seeming (to us) straight lines are really curves of an exceedingly small curvature, the Euclidian law is not touched. Of course, then, Prof. Clifford did not mean to assert that in a case in which the sides of a triangle are

not absolutely straight lines, it does not necessarily follow that the sum of its angles is equal to π: for Euclid himself is quite ready to admit that. No: Prof. Clifford must have meant that those three sides, though *absolutely straight* to us, creatures who can only imagine a homaloidal tridimensional space, are curved in a sense (thanks to a fourth dimension) which vitiates the Euclidian law.

Of course he may disclaim this interpretation: or he may assert that in the case supposed the three sides are both straight and curved, or neither straight nor curved, if such be his view. But until I see his disclaimer I shall hold that he meant to suggest to his audience that straight lines (proved to be so by the standard of straightness which is alone imaginable by creatures constituted as we are) are in another sense really curved, and as such afford an observable exception to the Euclidian Law. Now I say that, constituted as we are, we could have seen straight lines only as straight, and therefore we simply *could not* see those sides otherwise than as verifying that Law; and so we could never bring to the test of observation the question raised by the great quaternion of geometers; and therefore must for ever remain in absolute ignorance whether the space, in which we "live and move and have our being," be (in another relation) something different from what we find it to be in relation to our faculties.

Earthquake in Pembrokeshire

I HAVE received a letter from the west part of Pembrokeshire, dated February 3, from which the following is an extract:—

"Last Saturday, at 7 A.M., my bed shook twice under me; and at the same time the servant went into the dining-room, the fire-irons rattled and the room shook; an hour later, ——'s bed shook twice."

I do not know whether any notice has been taken of the occurrence elsewhere. I have paid some attention of late years to the indications of earthquakes in this neighbourhood, and am inclined to think that slight tremulous movements take place more frequently than may have been supposed or recorded. They would naturally be unnoticed in the daytime, and their detection would depend upon accidental wakefulness at night.

Hardwick Vicarage, Feb. 8 T. W. WEBB

Meteorology of the Future

IT is with some satisfaction that I have read in NATURE of December 12, 1872, the very interesting paper of Mr. J. Norman Lockyer, entitled "Meteorology of the Future," giving adhesion and the support of his name to the discovery of Mr. C. Meldrum, of a cycle of 11 years in the recurrence of the maximum of cyclones and rainfall in the southern hemisphere; a cycle corresponding with that already recognised in the maximum of sun-spots. But I have been somewhat surprised to see that my name has not been mentioned by Mr. Lockyer in reference to Mr. Meldrum's paper, as I have also published a paper on the connection of sun-spots with rainfalls, storms, cyclones, &c., prior to the first paper of Mr. Meldrum, which appeared in NATURE, October 24, 1872. Thinking that my paper has escaped your notice, and trusting that you might have some interest to see it, I take the liberty to forward it to you with this same mail. It was published in the *Boston Daily Advertiser*, November 2, 1871. Over a year has elapsed since its publication, and few are the days on which I had no opportunity of seeing the sun and scrutinising its spots with especial care, with the aid of telescope and spectroscope; and to-day I do not see the necessity of changing a word of the conclusions which I had come to in that paper. Only it appears that, in addition to the laws which I have drawn out, the position of the moon will have to be taken in consideration as a complicating element; as it seems that the conjunction and opposition have a tendency to increase the influence of the spots on our atmosphere, while the quadrature diminishes it in a certain measure. I could make some other remarks taken from my greater experience on the subject, but they are of secondary importance, and I will wait for another opportunity to publish them.

Perhaps I did not guard myself sufficiently in my paper, and have not explained with a sufficient amount of clearness, that though the effect of sun-spots on the weather is general all over the globe, yet the result cannot be expected to be absolutely the same; as local causes, very numerous, like mountain chains, forests, rivers, coasts, oceans, and climates, have an independent influence on the distribution of rains and the direction of winds, &c. But local causes are of a secondary order, and will be easily determined when once we are sure that the primary cause of atmospheric disturbances is to be found in the solar spots

Deep Wells

SINCE the question of the supply of water to deep wells was touched upon in NATURE (vol. vii. p. 177), in connection with the rainfall of 1872, I have been in hopes each week of seeing the subject thoroughly and scientifically discussed. It will be recollected that while we were all sneezing and spluttering, and thoughtlessly complaining of the long-continued wet, Mr. Bailey Denton deprecated the premature interference of the Archbishop of Canterbury with the rain, on the ground that the deep wells were not yet filled. This raised a great deal of discussion; people lost their tempers over the rain; and the country seemed to be divided into three bitterly hostile parties—the supporters, the opponents, and the suppliants of Providence. But still the geologists held aloof, and no one even answered the question, "What is a deep well?" but continued to talk as if wells were divided into two classes, deep and shallow, by a hard and fast line.

I therefore venture to hope that some geologist will take up the question in your columns, and give us a few facts instead of opinions. Meanwhile, I will state the case as it appears to me. With the exception of chalk and limestone formations, deep wells are, I believe, unknown in hills. In the side of a hill water comes naturally to the surface in a spring. Wells are only required—or, at all events, deep ones—at a distance from hills. They derive their water from water-bearing strata supplied in all cases either directly from hills, or indirectly from hills through the leakage of river-beds. No amount of rain falls upon cultivated, and therefore comparatively low-lying, land in Europe, sufficient to penetrate to even a shallow well through the earth immediately around it. This, at least, I presume to be the case, for 33 per cent. of their own bulk may be taken as an average amount of water for average soils to be able to retain and hold, so that if a well were 15 ft. deep to the top of the water it could not be affected by less than 5 ft. of rainfall, and when we deduct the enormous proportion of the 5 ft. that would be lost by evaporation and intercepted by vegetation, it is manifest that even 5 ft. of rain could not penetrate 15 ft. through any ordinary average soil. How, then, could any rainfall penetrate to a "deep" well of, say 100 or 200 ft. in depth?

Feb. 9 W. HOPE

THE GRESHAM LECTURES ON PHYSIC

THE Hilary Term Course of Lectures on Physic were delivered at the Gresham College, Basinghall Street, by Dr. Symes Thompson, on the evenings of the 17th and 18th ult., and the subject of the discourses upon this occasion was the important and interesting one of Contagious and Infectious Diseases. The professor started on his career of familiar explanation by describing two recent instances of outbreak of infectious disease in rural districts, in which the introduction and march of the fell agent of communication through the ranks of the small community could be distinctly traced. In the one case, the infection of scarlet fever was brought to the village of Flindon, in Hampshire, by a girl who came from Worthing, and served in a small general shop which was resorted to by all the villagers. Only two houses in the village that had children in them, escaped from the disease. In the other case, enteric fever was taken to Whitchurch, in Hampshire, by a young woman from Basingstoke, who returned to Basingstoke to die, after only six days' sojourn in Whitchurch. The fever, nevertheless, spread from the house in which she stayed, and within the next seven months there were seventy cases of enteric fever in a small community numbering only 1,450 people. The instance at Whitchurch acquired especial importance and interest, because it was made the ground for an investigation and report by the Local Government

Board, which now concerns itself with matters of this class. The inspector, Dr. Thorne, found that the place had been remarkably healthy until the potential cause, or infection, of the fever was conveyed to it by this chance visitant; but that it was most cunningly and elaborately prepared to receive and energise the deadly influence when once it came in the way. About one-third of the town stands upon the porous gravel of the alluvial bed of the river Test, and into this gravel, side by side, shallow wells were dug, to furnish the place with water, and pits were hollowed for the reception of all kinds of refuse filth and exuviæ incident to the conditions of life obtaining with a town community. Special care seems to have been taken to place the wells at a somewhat lower level than the pits containing the sources of pollution, whenever this was possible, as if to make sure that the liquid refuse should run into the reservoirs of the water; and in a few road-drains that had been laid down in the streets, commodious catch-pits were provided, to serve as traps and lurking-places for the offensive waste. Piggeries and small manure-yards were profusely scattered through the streets; and when once the enteric disorder had appeared, in order that it might have the fairest possible field for its operations, it became in some instances the practice to put sound people to bed with relatives actually suffering from the fever. In the case of Whitchurch, it amounts almost to a demonstration that the bowel discharges of the chance visitant from Basingstoke, containing the poison of enteric fever, must have been passed immediately into the water that was provided for the general service of the town; and that an exhaustless supply of the particular pabulum that is required for the elaboration of fresh quantities of the poison for the propagation of the malady, was kept ready on hand with the poison and the water. Enteric fever came by chance to the neighbourhood of Whitchurch; but, once there, it cannot be said that it made itself at home, and spread through the houses of the community by chance. The most elaborate provision had been made in the township to secure for it an easy resting-place, and a ready path of dissemination.

These cases of actual occurrence were happily selected by the Gresham Professor of Physic as the text of his discourse, because they aptly illustrate the value of the popularisation of information of this class, a result which it is the object of the Gresham College to insure. In the fever outbreak at Whitchurch, enlarged upon by Dr. Thompson, and from which something like every fourteenth member of the community was infected more or less gravely before the plague was stayed, nothing could be more clear than that the lodgment and seed-bed of the pestilence was prepared for it by human agency, but of course in entire ignorance of the dreadful work that was being performed. It is scarcely possible to believe that, if any single member of the constituted "nuisance authority" and "sewer authority" of Whitchurch had ever been present at the Gresham College when a lecture upon infectious and contagious disease had been delivered by the Gresham Professor of Physic in its theatre, there would have been an eight-months-long prevalence of enteric fever in the town.

The obvious, and indeed only certain, cure for evils of this character is the spread of sound information regarding matters that affect, and physically influence, health and disease, and the enlightenment of public opinion. The inhabitants of Whitchurch were the only people in this case who could possibly have been the efficient guardians of their own well-being.

Dr. Thompson designedly touched lightly upon the precise nature of the seed-germs of contagion; he satisfied himself upon this occasion by pressing home to the ordinary understanding, the great and incontrovertible fact, that diseases of this character, which sometimes decimate crowded communities, and which at all times levy a heavy tax upon human vigour and life, are caused and spread by influences which are well known to human intelligence, and largely within the sphere of human governance and control. Each form of infectious fever has its own characteristic habit and idiosyncrasy. Enteric fever and cholera tend chiefly to disseminate themselves through water, passing into the wells and fountains of daily supply, and at times travelling from house to house in the milk-cans of the easy-conscienced dairyman. Scarlet fever hybernates in a drawer, and after long months of seclusion comes forth with some old and cast-aside garment to be thrown with it round the throat or head of some new victim, and so to start thence upon a fresh career. Typhus fever crawls sluggishly almost fron hand to hand and mouth to mouth, and is immensely sociable and companionable in its spirit, languishing away when condemned to solitary confinement. Typhoid fever generates itself where filth, overcrowding, and impure habits of life prevail; and relapsing fever glides in the track of privation and misery. But the entire band of the ruthless co-fraternity agree in their subordination to known laws, and controllable conditions.

The beneficent influences and allies upon which human intelligence draws in dealing as efficiently and successfully as it now can with the work of controlling these evil ministrants, are, in the main, careful isolation of the sick; the preservation of the water from which daily supplies are derived in uncontaminated purity; the uninterrupted ventilation alike of hospitals and dwelling-houses, and fresh air; the immediate removal from the vicinity of active human life of all material contaminations that issue from the bodies of the sick, and the destruction of their morbific influence and energy by mixing them with antiseptic and disinfecting chemical agents such as carbolic acid, sulphuric acid, chlorides of lime and zinc, permanganate of potash, and charcoal; the preservation of the vital forces and resisting powers of the living frame by a well-ordered temperate rule of life, and avoidance of any undue indulgence in any kind of excess; and above all things the cultivation of an intelligent and ever enlarging familiarity with the great material conditions of nature that have been made the means of working out the marvellous arrangements and operations of civilised human life.

In considering the influence and powers of the various health-preserving chemical substances that are spoken of as antiseptics and disinfectants, it should be understood that agents of the character of carbolic acid, which are properly antiseptics, operate mainly by arresting the progress of fermentation and decomposition, while agents of the nature of Condy's fluid (permanganate of potash), chloride of lime, and especially charcoal, which are properly disinfectants, act by absorbing the noxious products of decomposition. Dr. Thompson very prettily illustrated this part of his subject by stopping the gradual evolution of bubbles of gas from a fermenting solution of sugar by adding to it a few drops of carbolic acid, and by showing that any drinking water that contains a hurtful trace of the rotten egg gas, sulphuretted hydrogen, immediately discharges the beautiful violet colour of Condy's disinfecting fluid. But his most telling illustration was the mortal remains of a defunct rat which he presented to his audience enshrined in a glass jar, and simply embalmed in charcoal. This rat was placed in the jar with the charcoal, at the termination of its natural life, some six or eight years ago; and from that time to this has been kept in the laboratory of Charing Cross Hospital for the greater part of the time with only a light paper cover over the jar. At the present time there remains of the rat's organism only the bones and a few hairs. But throughout the lengthened period of decomposition, no trace of disagreeable smell was at any time emitted. All gaseous products of decay were at once seized, and held by the charcoal.

THE BIRTH OF CHEMISTRY

VII.

Avicenna.—Albertus Magnus.—S. Thomas Aquinas.—Roger Bacon.—Raymond Lulli.—Arnoldus de Villâ Novâ.—George Ripley.—Basil Valentine.

THE Schools and Colleges of Arabia soon gave evidence of their value by the development of several considerable geniuses, whose works formed the text-books of Europe during a portion of the Middle Ages. Prominent amongst these learned Arabians was Ali-ben-Sina, or Avicenna, who was born in 980 in the neighbourhood of Shiraz. His abilities were considerable, and no pains were spared in his education; as a boy he read the Almagestum of Ptolemy, the Geometry of Euclid, and the Philosophy of Aristotle, and later in life he studied medicine with great success. We are told indeed that at the age of sixteen he was an eminent physician, and that at eighteen he cured a caliph of some grave disorder, and was hence promoted to great honour.

Avicenna is best known by his celebrated "Canons," which were translated at an early date into Latin, and often printed under the title of "Canones Medicinæ." This work has been translated into the languages of all civilised countries, and for no less than six centuries was the standard medical treatise of the world.

Avicenna also wrote on Alchemy and on Chemistry. If the works attributed to him are genuine he appears to have adopted the Aristotelian theory of the four mutually convertible elements. He speaks of air as the aliment of fire, and of the metals as compounds of a humid substance and an earthy substance. This last idea evidently arose from the observation of the calcination of metals. It was well known that if certain metals, such as lead and tin, are heated for a length of time in the air they are converted into a powdery substance or calx, and it was long before it was proved that this calx is not the metal from which one of its constituents has been expelled by fire; but, on the other hand, the metal combined with another substance. Avicenna divides all minerals into four classes; viz., (1) Infusible minerals; (2) Minerals which are fusible and malleable, that is, metals; (3) Sulphurous minerals; and (4) Salts. He noticed that mercury can, by heat, be caused to unite with sulphur and produce a solid body, having different properties from its constituents.

Avicenna was largely indebted for his knowledge to Alfarabi and to Rhazes. The latter wrote on medicine, and was one of the first to introduce substances formed artificially by chemical means into medicine.

Turning now our attention to European alchemists we meet at the outset with the name of Albertus Magnus (b. 1193, d. 1282), who became Bishop of Ratisbon in 1259. Various works on Alchemy are attributed to him: he wrote on the philosopher's stone, on the origin of metals, and on minerals; and he has described at some length various chemical operations, such as sublimation and distillation, and various forms of apparatus, such as aludels, alembics, and water-baths. He followed Geber in the belief that metals are composed of sulphur and mercury, and that different metals are produced by different combinations, and to some extent by the variations in the purity, of these substances. Albertus Magnus employs the term *affinity* (*affinitas*) to designate the cause of the combination of sulphur with silver and other metals; in this precise sense, applied to all cases of chemical combination, the term is used in the present day. He also speaks of sulphate of iron as *vitriol*, a name which it long retained. He describes the preparation of nitric acid, its principal effects upon certain metals, and its utility for separating silver from gold, inasmuch as it will dissolve the former and not the latter. Cinnabar, or sulphide of mercury, had long been known and used as a source of mercury; Albertus proved that it consists of sulphur and mercury by preparing it artificially, by subliming sulphur with mercury.

Albertus was not alone learned in Alchemy; he was a profound theologian, a scholar, an astronomer, a physician, and some said an adept in magic and necromancy. He embodied his wisdom in twenty-one folios, which were published in a collected form in 1651. M. Lenglet Dufresnoy, in his "Histoire de la Philosophie Hermetique," has mentioned several magical operations gravely attributed to Albertus Magnus by various writers. The most noticeable piece of magic was the sudden transformation of a winter's day into glowing summer:—"Horridam hyemem," says Trithemius, "in florigeram fructiferamque vertit." It is said that once during a very severe winter, he invited Count William of Holland, when he was passing through Cologne, to a feast. The Count, on his arrival with a considerable retinue, was surprised to find the feast spread in the garden, in which there were several feet of snow; and this treatment so angered him that he remounted his horse and prepared at once to leave his inhospitable host.

> Then the monk falling on his knees besought
> The Count to sit one moment at the board.
> He having done so, a most wondrous change
> Passed on the instant over all around.
> The dark clouds floated off, and left a sky
> Intensely blue, an air exceeding clear;
> The sun shone brightly, and the warm south wind
> Laved their pale cheeks and warmed them into life.
> They sit on greenest grass, the snow is gone,
> Sweet flowers bloom beneath their very feet,
> Ripe peaches blush upon the garden wall,
> And orange blossoms scent the humid air.
> A swarm of insect life on droning wing
> Is floating up above them in the breeze.
> The voice of birds is heard; the cooing dove
> Speaks softly to her mate; the nightingale
> Trills a sweet lay, half hidden in the leaves.
> All nature is most joyous in her garb
> Of brightest summer day, and all things seem
> To glory in the flood of warmth and light.

Upon this, the Count expressed considerable astonishment, as although he had heard a good deal of the magical powers of his host, he was quite unprepared to find him capable of changing the seasons. As soon as the feast was ended, Albertus Magnus repeated a magical formula—

> Now snow obscures the air, the flowers fade.
> The trees are torn by pitiless strong winds
> And weep their shrivelled fruit upon the earth;
> All sound of life is gone, a roar of elements
> Succeeds the plaintive quavering of the leaves.
> The birds fall dead to earth, and the dark air
> Betokens fearful tempests yet to come.

So the Count and his retinue rush off into the house to warm themselves, and thus ends the feast of Albertus Magnus. Some will have it that the story alludes to a winter garden, unknown at that time, which had been devised by Albertus for the preservation of rare plants. Middle Age books on science abound with such stories, and the belief in them was almost universal, as it well might be in an age in which the power of witches and wizards was acknowledged, and the raising of the dead was an admitted possibility. Brücker (*Institutiones Historiæ Philosophicæ*) says:—"Quæ enim de ejus convivio magico narrantur, merito inter inficeti seculi fabulas referuntur, quæ ex ignorantia rerum naturalium. eo tempore crassissima et Alberti mirabili rerum physicarum cognitione prodierunt."

In the church of S. Andreas in Cologne they show to this day the shrine and relics of Albertus—the accomplished churchman, scholar, magician and alchemist, of whom Trithemius says, "Magnus in Magia Naturali, major in Philosophia, maximus in Theologia."

Albertus had for his pupil the "angelic doctor," S. Thomas Aquinas (b. 1225, d. 1274), who was a great alchemist, and who wrote a treatise called "The most secret Treasure of Alchemy," together with some other works on the subject, which are equally obscure and unintelligible. He wrote also on the artificial preparation of gems, by fusing glass with certain substances, like oxide of copper, to communicate different colours; he mentions that if copper be heated with white arsenic, the former becomes white, something like silver. According to some, S. Thomas Aquinas was the first to employ the term *amalgam*, to designate a compound of any metal with mercury. S. Thomas was, like his master, a magician. We are told that between them they constructed a brazen statue, which Albertus animated with his *elixir vitæ*. It was useful as a domestic servant, but very talkative and noisy; nor could they cure it of this propensity. It happened one day that S. Thomas, who was a mathematician, was deeply engaged in a problem, but was continually interrupted by the talking statue; at length in a rage he seized a hammer and smashed it to atoms, to the great regret of his master.

Our great countryman Roger Bacon (b. 1214) also suffered from a charge of magic, and during his residence in Oxford was severely persecuted in consequence. He replied to the charges made against him by the admirable treatise "De nullitate magiæ," and in it clearly showed that what his contemporaries mistook for the work of spirits, were in good sooth the ordinary operations of Nature. In this work he speaks of gunpowder, although somewhat obscurely. "Mix," says he, "together saltpetre, *luru vopo vir*

con utriet, and sulphur, and you can make thunder and lightning, if you know the method of mixing them." Elsewhere he says, "a small quantity of matter properly manufactured, and not larger than one's thumb, may be made to produce a horrible noise and sudden flash of light." The third constituent of gun-

FIG. 11.—An alchemist hermetically sealing a flask containing a solution of gold.

powder is designated under the anagram *luru vopo vir con utriet*, for it was dangerous in those days to speak too plainly; indeed Bacon tells us that he adopted an obscure style both on account of the example of other writers, and of propriety, and also on account of the dangers of plain speaking. According to some writers, the following passage is to be found in Bacon's writings:—"Sed tamen salis petræ, *luru mone cap ubre*, et sulphuris, et sic facies tonitrum si scias artificium." Thus the saltpetre and the sulphur are directly designated, while the anagram *luru mone cap ubre* is convertible into *carbonum pulvere*, the remaining constituent—powdered charcoal. It is improbable that Roger Bacon invented gunpowder, although he was the first to know of its properties in England; he probably procured the knowledge from an Arabic source. Gunpowder was first used by the English at the battle of Crecy in 1346, 61 years after the death of Bacon; at this time it was apparently unknown to other European nations.

Roger Bacon is believed to have been far in advance of his times in all matters of science. To him has been attributed the invention of the telescope and *Camera obscura*, and several discoveries of a later date. The evidence is less conclusive than one could wish, but enough remains in his writings to prove that he was a very learned man and profound thinker. His "Opus Majus" clearly proves that he fully recognised the value of the experimental method, and of the inductive philosophy afterwards so ably advocated by his namesake Francis Bacon. Roger Bacon wrote largely on alchemy. Many of the alchemical MSS. in the British Museum are transcripts of portions of his works, among the more celebrated of which we may mention the "Medulla Alchymiæ," "Secretum Secretorum," and "Speculum Secretorum." He collected together the principal alchemical facts of his predecessors, and appears in many matters to have closely followed Geber. Bacon describes the distillation of organic substances, and alludes to the inflammability of the evolved gases. He proved that air is the food of fire by burning a lamp in a closed vessel.

Raymond Lulli (b. 1235) is by some asserted to have been a pupil of Roger Bacon. He was a voluminous writer on alchemy, his most celebrated treatise being his "Ultimum Testamentum." He also wrote on transmutation, on the Philosopher's Stone, and on magic. Lulli does not appear to have added to the chemical knowledge of his predecessors; he followed Geber closely, and was well acquainted with the processes and compounds which he describes. He describes alcohol under the names of *aqua vitæ ardens*, and *argentum vivum vegetabile*, and was in the habit of

FIG. 12.—Alchemical representation of processes.

rendering it anhydrous by allowing it to stand in contact with dry carbonate of potassium. He was also acquainted with ammonia.

Whatever Lulli's knowledge may have been, he obtained great reputation as a successful alchemist. He asserts in his "Ultimum Testamentum" that he converted fifty thousand pounds weight of base metals into gold. He is said to have been employed by one of the Edwards to make gold, and to have furnished His Majesty with six millions of money. Dickenson tells us that Lulli had a laboratory in Westminster Abbey, in which, after his departure, a quantity of gold dust was found.

Of the general tone and character of alchemical writings we shall speak more fully in the next article. Of the professors of the art little more need be said; a long list of names might be given, but it would be found that they did little to develop what afterwards became the science of chemistry. Let us glance at the work of a few of the remaining alchemists. Arnoldus de Villâ Novâ (b. 1240) was a great alchemist and physician, and the author of many works on the subject. His "Rosarius Philosophorum" purported to contain a key to all alchemical operations. He followed Geber closely. He considered a solution of gold the most perfect medicine, and we usually find that

such solution was recommended by alchemists as a necessary constituent of the elixir vitæ, and essential for the work of transmutation. In Fig. 11 the solution of gold in the flask is represented by the sun emitting rays. The simple disc of the sun is the more common symbol for gold.

Arnoldus also distilled various oils and essences. He contended that sulphur, arsenic, mercury, and sal ammoniac—all volatile bodies be it noted—are the souls of metals, and are given off during calcination. He also affirmed that silver is intermediate between mercury and other metals, just as the soul is intermediate between the spirit and the body. Arnoldus is said to have had for his pupil Pope John XXII., an accomplished alchemist, who left at his death eighteen millions of florins, which the alchemists fondly cite as a proof of the possibility of transmutation. Our own George Ripley, Canon of Bridlington in Yorkshire (b. about 1460) wrote a poem on alchemy, and passed for a successful disciple of the art, but we cannot point to a new fact which he elucidated. He divided all chemical operations into twelve processes—Calcination, dissolution, separation, conjunction, putrefaction, congelation, cibation, sublimation, fermentation, exaltation, multiplication, and projection. Several MS. copies of his poem exist in the British Museum, bound up with copies of the works of Roger Bacon and earlier writers. Here is a specimen of his rugged rhymes :—

> The fyrst chapter shall be of naturall *Calcination* ;
> The second of *Dyssolution*, secret and phylosophycall ;
> The third of our elementall *Separation* ;
> The fourth of *Conjunction* matrimoniall :
> The fyfth of *Putrefaction* then followe shall :
> Of *Congelation Albyficative* shall be the sixt,
> Then of *Cybation*, the seaventh shall follow next.

One of the most celebrated of the alchemists was Basil Valentine, who was born at Erfurt in 1394. According to Olaus Borrichius his works were accidentally discovered in the wall of a church at Erfurt many years after his death. A thunderbolt struck the church and exposed to view the long-lost alchemistical treasures. Basil Valentine was the author of many treatises, the most important being his "Currus Triumphalis Antimonii," in which he discusses the properties of antimony and of many of its compounds. He regarded the metals as compounds of salt, sulphur, and mercury ; and he was acquainted with many metallic compounds, among others nitrate of mercury, sulphide of arsenic, red oxide of mercury, chloride of iron, sulphate of iron, fulminating gold, carbonate of lead, acetate of lead, and the oxides of lead. He was aware that iron precipitates copper from solution, and that solution of potash precipitates iron from solution. He was well acquainted with the preparation of nitric and sulphuric acids, and used them for various purposes of dissolution. In order to obtain nitric acid he distilled powdered earthenware with nitre, or equal parts of nitre and green vitriol, or nitre with finely powdered flints. He obtained fuming sulphuric acid by distilling green vitriol, after the manner still practiced at Nordhausen and elsewhere. Basil Valentine wrote very obscurely and was fond of symbolical designs. Woodcuts 12 and 13 are taken from his works, and represent various processes imperfectly described. Thus the lion in Fig. 12 would represent a solution of a metal, the serpent another solution, or perhaps the serpent a metal, and the lion devouring it a solvent ; the sun and moon are watching the operation, and the symbol of mercury appears between two roses. Fig. 13 represents some operation which is thus thus described by the principal figure :—I am an old, infirm, debilitated man, my soul and spirit (represented by the two boy-headed birds above his head) leave me, and I assimulate the black crow. In my body are found salt, sulphur, and mercury. This may possibly refer to the solution of gold in aqua regia : it loses its metallic nature, its solidity and lustre, and assimulates the acid ; but one may conjecture in vain concerning the enigmatical devices in which some of the alchemists took so much delight, and which they often employed, like Roger Bacon's anagram, to conceal the full significance of their operations or discoveries.

FIG. 13.—Alchemical representation of processes.

The following extract, in which he treats of the generation of metals, will show the style of Basil Valentine's writing :—

"Therefore think most diligently about this; often bear in mind, observe, and comprehend that all minerals and metals together in the same time, and after the same fashion, and of one and the same principal matter are produced and generated. That matter is no other than a mere vapour, which is extracted from the elementary earth by the superior stars or by a sidereal distillation of the macrocosm, which sidereal hot infusion, with an airy sulphureous property, descending upon inferiors, so acts and operates, as in those metals and minerals is implanted spiritually and invisibly a certain power and virtue, which fume afterwards resolves in the earth into a certain water, from which mineral water all metals are thenceforth generated and ripened to their perfection, and thence proceeds this or that metal or mineral according as one of the three principles acquires dominion, and they have much or little of sulphur and salt, or an unequal mixture of them ; whence some metals are fixed, that is constant or stable ; some volatile and easily mutable, as is seen in gold, silver, copper, iron, lead, and tin."

Now this is by no mean the most obscure piece of alchemical writings with which we shall come in contact.

G. F. RODWELL

GLACIER MOTION

IN making some experiments on the freezing of water some time ago it was noticed that after the same water had been melted and frozen a number of times it generally burst the tube in which it was frozen. On looking for an explanation of this phenomenon, it became at once evident that the experiment contained the germ of the explanation of glacier motion. Every time the water was frozen in the tube there was a mimic representation of glacier motion. The ice possessed, the first two or three times it was frozen, a certain amount of viscosity which enabled it to adapt itself to the shape of the tube, as was evident from the distortion of the upper surface of the ice in the tube. How came the ice to lose this plasticity or viscosity, this power of adapting itself to the shape of the tube, the loss of which caused it to burst the tube after it had been frozen and melted a number of times? Wherein did the ice which had only been frozen once differ from the other? The answer to this seemed to be, that the ice which had only been frozen once had more air in it than that which had been frozen and melted a number of times, as each succeeding freezing deprived the ice of a quantity of air or some other gases. The natural conclusion, therefore, seemed to be, that ice with air in it is a viscous substance, though pure ice is not. The first question then to be asked is, Is ice with air in it a viscous substance? In order to get an answer to this question, glass tubes ·4-inch in diameter and twelve inches long were filled with water in which was dissolved a great quantity of air. The tubes were then placed in a freezing mixture. After the water was frozen in the tubes the tubes were

slightly heated and the rods of ice withdrawn from them and placed on two supports eight and a half inches apart, and a weight of one pound hung from the centre of these ice beams. The beams at once began bending and continued bending so long as the weights were left on them, thus proving the viscosity of the ice experimented on. The ice of these beams though similar was not the same as glacier ice; other ice beams were therefore made, in as close imitation of glacier ice as possible, which was done by placing a small quantity of water in the tubes, then some snow, and pressing it firmly to the bottom of the tubes, then adding more snow, and again firmly pressing it down, and so on till the tubes were filled, as much pressure being applied as possible to the snow to drive out the water. The tubes were then placed for some time in the freezing mixture. The ice beams were afterwards withdrawn from the tubes and placed on the supports, and a weight of one pound hung from the centre. The beams of snow ice so made were found to be more easily bent than those made from the water. The rate at which they bent varied, possibly owing to there being more or less water-ice mixed with the snow-ice: one of the beams bent one inch in five minutes. Temperature seemed to have some influence on the rate of bending of these beams, but this point was difficult to determine on account of the different beams bending at different rates at the same temperature; but so far as could be ascertained from the experiments, the beams bent slower the lower the temperature. The lowest temperature used in these experiments was rather more than three Fahrenheit degrees below freezing.

Smaller rods of snow-ice were then made ·2-inch in diameter, and as it was found that these could be easily bent in the hand, it was thought possible to bend them into rings. In attempting to bend these rods round a cylinder three inches in diameter, a difficulty was met with. After the pressure had been applied a short time, and before the circle was half turned, the rods always broke with a pressure which they easily bore at the beginning. Here, then, was a difficulty. The explanation seemed to fail at the last moment. The bending had so altered the structure of the ice, that it had lost much of its viscosity and become brittle. How then are we to account for glacier ice keeping its viscosity after years of bending. On examining the fracture of the beams it appeared as if a fibrous structure had been developed in the ice by the bending. The fracture did not go straight across, but part of it ran parallel with the axis of the beam, strongly resembling the fracture of poor bar iron, crystalline at one part, fibrous at another. The bending of the ice had evidently developed a laminated structure in it, similar to that found in glaciers. This laminated structure was developed along the beams, as was to be expected; for the direction in which this structure will be developed depends more on the direction in which the particles of ice are caused to slip over each other, than on the direction in which the pressure or tension is applied. The bending having produced this laminated structure in the ice, it is evident that the beams will be weaker after this structure is developed than before, on account of the cohesion of the ice being weakened along the planes of lamination. It was thought therefore that if the pressure was taken off the ice so as to relieve the particles from strain and stop them sliding over each other, that the laminæ which had been developed in the ice, would, so to speak, become welded together, and the strength and plasticity of the beam be restored. Acting on this supposition an attempt was again made to bend the ice-beam into a circle. After a small part of the circle had been turned, the pressure was taken off the beam and a short time given for the particles to rearrange themselves; the pressure was then again applied, a small part more bent and so on. When done in this way it was found that the ice-beams were easily bent into a circle, the ends were then united by means of pressure, and a solid ring was thus produced from a straight beam of ice. These conditions of alternate rest and pressure are in all probability those which exist in glaciers. After pressure has acted at one part of the glacier, bending takes place, so relieving the ice at that part from the pressure, which comes to bear on another part of the glacier; and before the pressure again comes to bear on the first part its strength and plasticity or viscosity has been restored by rest.

Although ice under certain conditions has by these experiments been shown to be a viscous substance, to have the power of changing its shape and so enabling it to flow—though slowly—in its channel; although it has thus been shown that the viscosity of ice is a cause of glacier motion, yet it must not, therefore, be concluded that it is the only cause. Among other causes which may assist in producing glacier motion may be mentioned: 1st. The sliding of the ice over its channel; this sliding being assisted by the tendency which the ice has to melt where it rests on its channel. 2nd. The melting of the ice in front of obstacles, the melting being produced by the melting point of the ice in contact with the obstacle being lowered by the pressure of the ice behind. 3rd. The melting of the ice in the body of the glacier, by heavy pressure being brought to bear at certain points, part of the water so formed finding its way to the channel under the ice, and part being re-frozen. 4th. The crevasses in the glacier formed by the fracture of the ice. This breaking up of the ice will enable large masses of ice to move into different positions relatively to each other, much more easily than if the ice was solid. This breaking up of the ice will also make the motion due to its viscosity take place quicker than if the ice was in one mass. 5th. The old dilatation theory explains something of the motion of glaciers, though it may not explain how that motion takes place, yet it accounts for some of the pressure which produces that motion.

JOHN AITKEN

SUB-WEALDEN EXPLORATION

SINCE the last quarterly report, troublesome accidents have delayed this undertaking. On the very day of the meeting in Jermyn Street in December last, the drilling tool broke off close to the edge, leaving a flat chisel (9 in. wide tapering up to 2 in.) at the bottom of the bore. A fortnight was lost in the endeavour to extract it. Mr. Bosworth's ingenuity and patience were sorely tried; but he at last succeeded in bringing it to the top from a depth of about 96 ft. 34 ft. consisting of narrow bands of calcareous shale, alternating with argillaceous limestone in layers of from 4 to 6 in. were passed through; but on January 28, at 131 ft. from the surface, a bed of pure solid white gypsum 4 ft. in thickness, was reached and perforated, the new trifid drilling tool bringing up solid cores. This is the first time a bed of gypsum of this character has been found in Sussex, and it probably indicates the presence of the Purbeck beds. If so, strata hitherto unknown to exist in Sussex are now added to our geological information, and the scientific world will have its interest re-awakened to this, the first boring attempted in England for purely scientific purposes. Boring is a tedious and expensive process, and we hear that the preliminary cost of machinery has exhausted the treasury. Subscriptions are earnestly requested to complete the second sum of 1000*l*. promised on condition that 2000*l*. be raised. Mr. Henry Willett, Arnold House, Brighton, will be pleased to receive any sums for the purpose. It would be a great disaster indeed if the boring had to be stopped for want of funds; but we feel sure that when the state of matters is made known to the friends of science Mr. Willett will soon have to report a full treasury.

NOTES

THE candidates for the chair of Geology held by the late Prof. Sedgwick now stand as follows:—Mr. Morris, Lecturer on Geology at University College, London, and a Vice-President of the Geological Society; Mr. P. Martin Duncan, F.R.S., also a Vice-President of the Geological Society, Professor of Geology in King's College, London, and Lecturer at the Indian College of Civil Engineering at Cooper's Hill; the Rev. Osmond Fisher, formerly Fellow and Tutor of Jesus College, Cambridge; the Rev. T. G. Bonney, Fellow and Tutor of St. John's College, Cambridge; Mr. Boyd Dawkins, F.R.S., formerly on the Geological Survey, and now Director of the Museum and Lecturer in Geology at Owens College, Manchester; Mr. A. H. Green, of the Geological Survey, formerly Fellow of Gonvillle and Caius College, and now Lecturer in Geology at the School of Military Engineering at Chatham; and Mr. Hughes, of Trinity College, also on the Geological Survey. Mr. Morris has acted for the last two years as deputy to the late professor.

A CORRESPONDENT in Paris informs us that M. Janssen was to be nominated to a vacant place in the French Institute last Monday, and that there is every likelihood of his obtaining a majority of votes when the election takes place a few weeks hence. M. Janssen is to be sent to Pekin in December 1874, for the purpose of observing the transit of Venus.

PROBABLY the first telegram transmitted by the Atlantic cable, under the generous arrangement mentioned in NATURE of January 30 last, was received by the Astronomer Royal on February 7, and forwarded to us the same day. It announced the discovery of a new planet, No. 129, of the 10th magnitude, on the night of February 6: R.A. $9^h\ 16^m$ north decl. $15°\ 38'$. Such an excellent arrangement is likely to save all disputes as to priority of discovery.

PROF. FLOWERS'S Hunterian Lectures at the College of Surgeons for this year will treat of the Osteology and Dentition of Extinct Mammalia, with their geological and geographical distribution and relation to existing forms. The course commences on Monday next (the 17th) at four o'clock, and the lectures will be continued at the same hour on Mondays, Wednesdays, and Fridays until March 28. It may not be generally known that this course is open to all who wish to attend, without fee or any formality.

DR. T. R. LEWIS has made the important discovery of a haematozoon, which he has provisionally named *Filaria sanguinis hominis*. In a paper lately published at Calcutta, he describes its discovery last July in the blood of a patient suffering from a disease well known in tropical countries, Chyluria. The worms appear to be present in very large numbers in the blood and in some of the secretions; indeed, they were first observed in the urine two years ago. They are evidently hematoids, but sexual distinctions have not been hitherto observed, nor is anything known of their ova or development, nor how they gain an entrance to the body. Each is inclosed in a hyaline sheath, in which it can contract and expand itself, so that they may be probably regarded as in an encysted form. The average length is ·175 of an inch, the breadth about that of a red blood-disc; they are therefore much smaller than the Guinea-worm or *Trichina spiralis*. The disease of which it is probable that they are the cause is not rare in tropical countries, and is sometimes fatal. This curious "Filaria" was discovered independently in chylous urine, by Dr. Lewis and by Wucherer, in 1870. Dr. Crevaux, of the French navy, published a memoir on the same subject a few months ago ("De l'Hematurie chyleuse ou graisseuse des pays chauds;" A. Delahaye, Paris, 1872). In the Montpellier *Revue des Sciences Naturelles*, for September, 1872, Dr. A. Corre figures and describes some specimens as transparent, colourless, and varying in size from ·2 to ·265 of a millimetre long, by ·006 to ·007 broad at the thickest part. This exactly corresponds with the diameter of a human red blood-disc, as given by Welker. He has sometimes observed a slight constriction below the head, as has Dr. Crevaux, who also noticed the dark spot supposed by Dr. Lewis to be a mouth, "qui ressemble plutôt à un amas de granulations qu'à un orifice." MM. Crevaux and Corre have been unable to distinguish any organs, only granulations forming a central line down the body, "qui simule, au premier aspect, un canal étendu de la tête à la queue." Wucherer regards the worm as probably a larval form. It is important to remark that the cases examined by their authors were all from tropical America. The descriptions and the drawing referred to abundantly confirm Dr. Lewis's admirable observations, though they are not nearly so complete. To him belongs the undivided merit of discovering this parasite in its true *habitat*, the living blood.

THE Director of the Observatory of Harvard College purposes to publish a series of astronomical engravings, which shall represent, as nearly as possible, the most interesting objects in the heavens, as they are seen with the powerful instruments of the observatory under his charge. The series will consist of at least thirty pictures, and will embrace the principal planets, moon-craters, sun-spots, solar prominences, nebulæ, and spectra of variable stars. To obtain some assistance towards defraying the expense of printing, as well as to secure for them a more general circulation than can be expected for volumes of annals of an observatory, they will be offered to subscribers at the rate of 2*l*. 10*s*. for the set. The engravings will be delivered from time to time as they are completed, and they will be followed by some pages of notes and explanations. Messrs. Trübner and Co. are instructed to register the names of intending subscribers.

THE American Government has established an Observatory at Fort Garry, Manitoba, which is, as nearly as possible, the central spot of the American continent.

AMMONITES have been discovered by Dr. Waagen ("Memoirs of the Geological Survey of India, IX.") in a carboniferous formation near Jabi, north of Shabpoor, in the N.E. of the Punjab. The form appears to be allied to some species found in the Whitby lias. The presence of this family in palæozoic rocks is a new and important observation.

SOUTH AFRICAN sportsmen have got a bad name among many people, the increasing scarcity of the various kinds of so-called "big game" being commonly attributed to their exploits. There are those, however, who think otherwise, and believe, as is doubtless the case, that the deeds of an occasional Gordon Cumming, who makes a shooting excursion up the country, had little lasting effect upon its animal and particularly its mammalian life, the decrease in which is mainly caused by the spread of settlements. The University of Cambridge seems to be of the latter opinion, and on Thursday last, by grace of the Senate, authorised the payment, from the Worts' Travelling Bachelors' Fund, of 200*l*. to Mr. T. E. Buckley, F.Z.S. and B.A. of Trinity College, who is about to make an expedition into the interior from Natal, for the purpose of forming natural history collections, and especially of obtaining skeletons of the larger animals, with the understanding that specimens be sent to the Museum of the University, accompanied by reports. Mr. Buckley has had much experience as a traveller, having visited some of the wildest parts of Lapland, explored Turkey, and braved the dangers of the Gold Coast: and he has contributed, in conjunction with his fellow-voyagers Captain Elwes and Captain Shelley, to the *Ibis*, good accounts of the ornithology of the two countries last mentioned.

A SEVERE shock of earthquake was felt at Lahore on January 1, at 7.55 A.M. and at Suchin on December 31. The

earthquake, which on December 15 was felt at Lehree in Eastern Cachi and Zehri and the Scinde frontier of India, was also felt at Dadur, Suhwan, Shikarpore, and Jacobabad, within British territory.

In the beginning of January a sharp shock of earthquake was felt in the island of Imbros, opposite the Dardanelles. Several small works were destroyed, and other damage done. This was, perhaps the same as the earthquake felt on January 13 at Gallipoli, and Chanak, Kalehsi (Dardanelles), at about 10.30 A.M. The oscillation was from S. to N. This earthquake was slightly felt at Constantinople, but not at Smyrna.

The Royal Commission on Scientific Instruction met on Tuesday and Wednesday of the present week.

We learn, from the *British Medical Journal*, that Dr. Struthers, Professor of Anatomy at Aberdeen, gives free evening lectures on this subject to students of Divinity and Arts, and to all who take an interest in Natural science.

We have received an "Extract from the Science Directory, revised to November 1872," showing the nature and amount of assistance afforded by and through the Science and Art Department to Instruction in Science. This gives all the information needed both by pupils or teachers who are desirous of qualifying themselves to participate in the various grants, scholarships, exhibitions, prizes, &c., by which Government seeks to encourage scientific education. Since the publication of the last directory, several alterations have been made in the administration of this department. One is that grants are given to encourage the construction of special laboratories in Schools, and collections of apparatus adapted to teaching will be sent on loan to schools under certain conditions. For the year 1873 arrangements will probably be made to enable a certain number of teachers to stay about six weeks in London, to undergo a course of instruction in teaching certain special subjects. Several improvements have also been made in the course of instruction for students who have completed their course at the ordinary Elementary School. These alterations all tend in the direction of greater stringency and thoroughness, and an attempt has been made so to frame the course, as to lay the foundation of a systematic scientific training.

We with pleasure notice that a new local scientific society has been started at Kensington, under the title of the Kensington Entomological Society. There are now a considerable number of similar societies in the London suburbs, and we hope this one will meet with encouraging success, and produce some work of lasting value. We hope next week to give a paper read to the Society by Mr. A. Murray, 67, Bedford Gardens, Kensington, who, we have no doubt, will be glad to furnish information to anyone desirous of joining the Society.

We are glad to see one more provincial paper devote some of its space to Science. A copy of the *Leighton Buzzard Observer* sent us devotes a whole column to scientific jottings, selected with considerable judiciousness.

Mr. G. St. Clair, in reference to his letter of last week, sends us a letter from the *Manchester Guardian*, of February 5, which says that the writer and two friends were walking down Oxford Street, Manchester, about 10 P.M., when suddenly the place was illuminated with a bluish light equal to the light of mid-day, and right over their heads burst, as it were, a ball of fire; instantly it shot through space, when it burst again, and finally disappeared. After a few seconds more they distinctly heard the sound of a report like thunder. The course of the meteor appeared to them to be from east to west; the time was about seven seconds.

A Medical Society has been formed at Smyrna, on the basis of the Imperial Medical Society at Constantinople.

The Abbé Moigno, after all, has brought his *Salles du Progrès* to a termination; not, however, we are glad to learn, because his praiseworthy scheme of popular education has turned out a failure, but because he has found another means of accomplishing his "great object of intellectual regeneration by true science, good and beautiful." The founders of the Catholic Circle of Workmen—a scheme apparently meant for the elevation of the French working classes—have proposed to make use of the Abbé's services, his educational staff and *matériel*, to carry out their educational plans both in Paris and in the provinces. He has, we think wisely, accepted the offer, and, although he has been compelled to terminate his own particular scheme, he will be in a much better position for accomplishing the admirable end he has in view.

Mr. W. B. Gamlen, M.A., of Exeter College, has been elected Secretary to the Curators of the Oxford University Chest.

The following information has been sent us by the scientific editor of *Harper's Weekly*:—Prof. Powell has returned from the exploration of the Colorado River of the West, having completed the examinations of the wonderful series of cañons along the course of this river about October 1 last. He then visited a group of volcanic mountains north of the Grand Cañon, composed of about sixty basaltic cones, to which he has given the name of Uinkaret Mountains (the Indian name, signifying "Where the pines grow"). An extensive series of faults has been examined by the party this year. These run in a northerly and southerly direction across the Grand Cañon, and north into the plateaus at the head of the Sevier, and some as far as the Wasatch Mountains. They are from 50 to 200 miles in length, and the drop from 100 to 3,000 ft. The fissures of these faults have been vents for volcanic eruptions, and along their courses vast floods of lava have been poured out and cones built up. A number more of the ruins of ancient communal houses have been discovered, making in all more than a hundred so far found by the party in the valley of the Colorado. One of these was situated on the crater of a volcanic cone. The collection of picture-writings (etchings on the rocks) has been much enlarged; and the seven ancient towns, called by the Spaniards the Province of Tusayan, have been revisited for ethnological purposes. The professor has also continued his studies of the Ute Indians. He has discovered among them an extensive system of mythology and a great number of rude songs, and brought with him a large collection of articles illustrating the state of the arts among the people who inhabit the valley of the Colorado, composed of stone implements, pottery, basket-ware, clothing, implements for hunting and entrapping animals, musical instruments, ornaments of feathers, bones, teeth, and claws, and various miscellaneous articles. Prof. Thompson remains in the field for the purpose of extending the exploration north, toward the Wasatch Mountains.

An article by Herr von der Wengen, on the artificial breeding of salmon in Silesia during the season of 1871 and 1872, published in the circular of the *Deutsche Fischerei-Verein*, contains some very interesting facts in reference to this fish. As the result of four successive years of observation, he remarks that he finds salmon generally descend to the sea in the second year, and remain there not one year, as is so generally assumed, but more nearly two, before returning to the river and home of their youth. The establishment at Hammel, which has already done so much to increase the stock of salmon in the Upper Weser, has determined, from numerous observations, that a period of four years elapses between the birth of the salmon and its first return from the ocean.

OSCAR GRIMM describes Bacteria and Vibriones from his own investigations in the *Archiv fur Mikrosc. Anatomie.* He has observed their conjugation and fissiparous multiplication, and also has seen leucocyles breaking up into granular matter which ultimately assumed the form of Bacteria.

PROF. MOLLER, of Lund, Sweden, has published the Ephemerides of Faye's comet for its next return to the neighbourhood of the sun. It will be in perihelion about July 18, and will continue to approach nearer and nearer to the earth till Jan. 10, 1874. It will not, however, be in a position favourable for observation, and it is very probable that not even the most powerful telescope will be able to catch it.

M. CALLAS in *Les Mondes* endeavours to account for a dry haze (*brouillard sec*) which is seen in the atmosphere at certain seasons in particular countries. At Paris he says it is clearly visible on the horizon on the morning of lovely summer days, and is regarded as the presage of fine warm weather. It is of a light roseate hue. In proportion as the day is dry and warm, the denser and higher above the horizon is the haze. This haze is seen at all heights, having been observed by Saussure in Switzerland, by Lecay and Charles Martin in Auvergne, and by Wilkomer in Spain; in all cases, the phenomenon is seen at its best when the day is dry and warm. M. Callas attributes it to the combustion of aerolites and shooting stars. The attraction of the earth, he says, causes these bodies to deviate from their regular course and to be precipitated to the earth's surface with a rapidity which certainly exceeds 20 kilometres per second, and which is sufficient to set them on fire and render them volatile. The vapours thus produced rapidly become so rarified that they may be looked upon as the ultimate limit of divisibility of insoluble bodies and form the dry mists alluded to. Obeying the law of gravity these descend to the earth from the heights where they are formed, slowly however, on account of their extreme tenuity. As they approach the earth they come under the influence of winds which dissipate them, and of cold moisture, which absorbs them. Hence it is that they are perceived only in certain countries and in warm seasons; especially in Spain, and on the table-lands of Abyssinia and Mexico. M. Callas thinks that the haze may be regarded as a sort of cosmical matter akin to that which composes the tails of comets. The hypothesis has the merit of being at least curious, and so far as we know, original.

THE first paper in the last number of the Bulletin of the French Geographical Society is in connection with a well-executed map of the chief physical features of Eastern Brazil, appended to the number. M. Charles Grad contributes a long article on the geology of the Algerian Sahara and its system of waters. Perhaps the most interesting article is by M. Paul Gaffanel on the Great Sargasso Sea in the middle of the Atlantic, the history of which he traces from the Phœnicians downwards, describes its geography historically and with reference to what is known of it at present, which seems to be comparatively little, and concludes by pointing out that the wrack or algæ of which it is composed might be put to immensely profitable industrial uses.

WE have received the prospectus of the new Italian Geographical Magazine, whose first appearance we announced last week. Dr. Petermann has written a very hearty preface for his young friend, the editor, Guido Cora, whose plan is very comprehensive, embracing not only geography proper, but also geognosy, botany, zoology, anthropology, ethnography: hence the name of the magazine,—*Cosmos*. We wish it ample success.

THE *Revue Scientifique* for Feb. 8 contains Dr. Liebreich's Royal Institution lecture on the effect of School Life on Vision in the Young.

*SIR W. ARMSTRONG ON THE COAL QUESTION**

II.

AT the present moment attention is being drawn to a new method of increasing the efficiency of the steam engine by pumping heated air into the boiler. It is impossible to conjecture what theoretical considerations could have led Mr. Warsop, the discoverer of the system, to anticipate beneficial results from the adoption of such an expedient, and yet the experiments that have been made in proof of its efficacy are so authoritative that they cannot be repudiated on the ground of their being unsupported by theory. This subject, although much debated of late, is still so ambiguous and obscure that I shall take the present opportunity of stating the difficulties of the case in the hope of eliciting satisfactory explanation. Mr. Warsop's method consists in attaching to a steam engine a forcing pump for the purpose of injecting air into the boiler. The pipe from this forcing pump is formed into a coil in the flue so that the air may absorb a portion of the waste heat. After entering the boiler the pipe is laid along the bottom, and being perforated with holes allows the air to bubble up through the water at many different points. The result appears to be that, with a given expenditure of fuel, the available power of the engine is considerably increased by the action of the air-pump, notwithstanding that the power for working it is derived from the engine itself. How, then, is this to be explained? It is clear that air forced into a receiver cannot without the aid of extraneous heat give back all the power expended upon the forcing pump. There must of necessity be loss of power by friction, and also from the impossibility in practice of realising all the expansive action of the condensed air corresponding to the compressive action of the pump prior to actual injection taking place. It would be a liberal estimate to assume that one-half of the power expended on the pump is recoverable from the air. Hence, to make up the deficiency by the application of heat, we should have to double the volume of the air, which would require it to be heated to upwards of 500° F, above its initial temperature. Now, in the case of the Warsop arrangement, considering the inconsiderable heating power of the escaping gases to which the air-pipe is exposed; considering also the slow absorbing power of air, and the smallness of the surface presented by the coiled pipe, it is hard to believe that the air could enter the boiler at such a temperature as I have named; but even if it did, where is the surplus power to be found that gives the engine a palpable increase of efficiency? The mere reaction of the compressed air, with all the aid it can possibly derive from the absorption of waste heat, would barely save a loss, and certainly could never account for an important gain. It seems obvious, therefore, that whatever beneficial action is exercised by the air must be of an indirect nature, and not the immediate effect of its mechanical energy.

Four modes of action have been put forward to account for the effects obtained. Firstly, it is said that the air, in bubbling through the water, facilitates the disengagement of the steam. This may very possibly be the case, for we know that water, entirely deprived of air, may be heated in an open vessel to a temperature greatly exceeding the usual boiling point, before ebullition commences. The reason of this is, that the adhesion between the water and the containing vessel, and also between the particles of water themselves, is sufficient to restrain the formation of steam at the usual boiling heat, unless air be present to afford points of separation. So far the explanation is plausible; for if the abstraction of air from water raises the boiling point, we may infer that the addition of air will lower it. But the reduction of the boiling-point within any supposable limits, would not lessen the quantity of heat required for the production of the steam sufficiently to afford a solution; because the sum of the latent and sensible heat, though not constant, as was formerly supposed, does not vary in relation to the boiling point to such an extent as would account for any important saving in that direction. A tangible advantage might, however, accrue from the accelerated transmission of heat from the fire to the water, caused by the increase of difference which a lowered boiling point would occasion between the temperature of the water and that of the fire and gases acting on the boiler; but in the absence of thermometric experiments to show how much the boiling point is actually reduced, and how much the escaping gases are cooled, it is impossible to form any definite opinion as to the amount of this saving. It is certain, however, that unless the reductions of temperature be greater

* Continued from p. 272.

than can be readily conceded, they will not be sufficient to account for so large an economy as is said to be realised.

Secondly, it is argued that the bubbles of air virtually afford an extension of heating surface. So they do, in relation to the heat carried in by the air; but the air can only part with its heat by lessening its direct contribution to the power of the engine. Moreover, if the heat carried in by the air be insignificant in quantity, as I believe it to be, the explanation fails in every point of view.

Thirdly, it is stated that the action of the air prevents and even removes incrustation, and thereby keeps the heating surfaces free from all obstruction as regards the transmission of heat. Very careful observation would be required to establish this fact; but, granting the fact, it would follow that the advantage of injecting air would be limited by those cases in which deposit would otherwise be formed. In a boiler perfectly free from incrustation the injection of air ought to be nugatory, but this does not appear to be the case.

Fourthly, it has been ingeniously suggested by Mr. Siemens that the air passing with the steam into the cylinder may form a film on the interior surface capable of arresting, in a great measure, that condensation which is known to be so wasteful of power in unjacketed cylinders, where the steam is used expansively. It is highly probable that the air would really accumulate in this manner against the sides of the cylinder; because, while the particles of steam sank down into water, the particles of air would remain. It is also pretty clear that this film of air would intercept the abstraction of heat by the cooled material of the cylinder; but if we admit this mode of action, then it would seem to follow that it is only in the absence of a steam jacket to the cylinder that the economy of injecting air is realised, and in fact that the injection of air is merely a substitute for steam jacketing. Moreover, if such be the action of the air, pumping into the steam should, in this point of view, produce the same effect as pumping into the water.

I have dilated upon this subject more, perhaps, than necessary, but I have done so with a view to stimulate action in the matter, for it is time that the doubts and obscurities which beset the system should be cleared up, and its adoption or rejection be brought to an issue. There is no class of steam-engine in which economy of fuel is of so much importance as it is in marine engines, for not only is it an object in steam navigation to diminish the cost of coal, but it is a still greater object to save room, and thereby increase the space available for cargo. The introduction of compound engines has enabled steam to be used of much higher pressure than formerly, and with greatly increased expansive action. The result has been a saving of about 50 per cent. in the consumption of coal, and I believe I am substantially correct in saying that in steam vessels, employed on long voyages, this saving of coal has been attended with a fourfold increase of the previous carrying power. It is highly probable that still further reductions ot fuel will be effected by following in the same path, which has already lead to such great economy. The pressure of steam in marine engines is still far inferior to that which is used in locomotive engines, and there is no obstacle, of an insurmountable nature, against the expansive action being increased proportionately to any further increase of pressure.

But our efforts to increase the efficiency of marine engines must not run too much in one groove. Recent improvements have been almost exclusively directed to the mode of *applying* the steam, and but little attention has been paid to the mode of *producing* it. The engine has advanced enormously in improvement, but the boiler has actually receded; for we now get less evaporative effect from marine boilers than was obtained from those previously in use. This diminution of effect has resulted from changes made in the form of the boiler, to enable it to resist the greater pressure of the steam; but there is no inherent necessity for sacrificing evaporative power to meet this requirement, as is proved by the example of the locomotive boiler, which, while it produces steam of double the pressure of that supplied by marine boilers, stands unrivalled in regard to evaporative effect. The superiority of the locomotive boiler in regard to evaporating power is chiefly due to the large capacity of its fire-box, which affords ample space above the surface of the fuel for perfecting the combustion of the gases. In the old form of marine boiler the flame space above and beyond the fire was also very large, and the evaporation per pound of coal was nearly as great as in the locomotive. But this advantage has been sacrificed in the modern form of boiler, by adopting a cylindrical fire chamber within the boiler. This form is very favourable to strength, but it affords very little head-room over the fire, and the consequence is that, although the tubular heating surface is relatively as great as before, the evaporation per pound of coal has fallen considerably. I do not say that the locomotive form of boiler, pure and simple, is that which ought to be adopted for marine engines, but it is well worth consideration, whether by adopting the same principle of construction, a more efficient boiler would not be obtained for marine engines. A more powerful draught would probably be required than is now necessary, but this could be obtained by known mechanical methods, applied either to *draw* air through the furnaces, or to *force* it into a closed stoke-hole. The production of draught by auxiliary power, would have the great advantage of enabling the rate of combustion to be regulated at pleasure, so as to meet the varying demand for steam, and it would also facilitate the application to marine boilers of mechanical firing, which does not succeed with a slow draught, and requires a variable draught to meet the fluctuating production of steam required at sea. The great number of stokers required in large steamers, the severity of the work, and the inefficiency of the method they pursue, as evidenced by the dense clouds of smoke they produce, render the introduction of mechanical firing in such vessels a matter of the utmost importance; and I do not believe that any of the difficulties which appear to stand in the way are incapable of removal.

I must not dismiss the subject of steam power without some allusion to its application to agriculture. In no description of steam-engine has economy of fuel been more perseveringly and successfully followed out than in engines for agricultural use; and Mr. Bramwell, in his late address to the Mechanical Section of the British Association, does full justice to the mechanical engineers who have been the means of bringing these engines to such a high degree of efficiency. It is satisfactory to see that the application of steam to the cultivation of the land, and to every kind of farming operation, is rapidly extending; for if the food producing power of the land has to be increased, it must be by substituting, as far as possible, the comparatively cheap power of steam, for the labour, both of men and horses. The greatly increased demand for labour in manufacturing occupations, as well as for mining and constructive purposes, will certainly diminish the supply of rural labour and increase its cost. Such a result is not to be regretted, considering how miserably ill requited farm labour in most parts of England has been; but unless the growing cost of agricultural labour and of horse work can be counterpoised by a more extensive use of steam power, we may expect much of the land in this country to be thrown out of cultivation. Very different are the views of those who maintain that food would be more economically produced by increasing, instead of diminishing, the labour employed on the land. Such is the doctrine of those who advocate the parcelling out of the land in small plots to peasant holders, and who even contend that waste lands, incapable of profitable return by ordinary treatment, could, by this means, be advantageously cultivated. It would, indeed, be a retrograde step to renounce the aid of capital and mechanical skill in tillage, and fall back upon the primitive system of spade husbandry. If there be a country in the world where such a mode of cultivation is the best, that country is assuredly not England, where all the resources of science and skill are necessary to the maintenance of a large population, under adverse conditions of soil and climate, and where labour is more highly paid in manufacture than in agriculture.

I have had considerable personal experience of steam cultivation, and am a thorough believer in its efficacy; but I may here draw attention to a very general subject of complaint concerning the machinery and implements employed for the purpose. I refer to the frequency of breakages due to insufficient strength in the construction. If makers of the apparatus, used in all the varieties of steam tillage, could only be induced to be more liberal in the use of material, the introduction of their machines would be very greatly accelerated.

I must also touch upon the subject of steam traction on common roads, which has lately received a considerable impulse from the introduction of Mr. Thomson's invention of India-rubber tyres. The number of horses in this country is enormous, and being great consumers of food, their maintenance is a heavy charge on the resources of the nation. Next to human power, horse power is the most expensive that we can use, and we may welcome the dawn of a period when steam will, to a great extent, supplant animal power in our streets and highways.

But these, and all other extensions of steam power, involve greater consumption of coal, and we may well look with anxiety to our diminishing stock of this precious mineral, which, when once expended, can never be replaced. It will therefore, be a fitting conclusion to this address briefly to review the results arrived at by the late Royal Commission, of which I was a member, as to the extent of our available coal and its probable duration. I will not trouble you with the vast amount of detailed information collected by the Commissioners as to the extent of the British coal fields, nor with the elaborate calculations of the quantities of coal which those coal fields contain, but I will chiefly direct my observations to those points of the inquiry which fall within the province of mining and mechanical engineering, and to the broad conclusions at which the Commissioners arrived.

It being well known that a great extent of our coal lies at depths greatly exceeding those of our present deepest mines, it was essential to the inquiry that the limit of possible depth of working should be approximately defined. One of the committees, therefore, into which the Commission was divided, was entrusted with this branch of the subject, and having acted in the capacity of chairman to that committee, I am especially familiar with its proceedings. It fortunately happens that water is never met with in large quantities at great depths, and it is easy to exclude it from the upper portion of a deep shaft, by the modern process of encasing the shaft with cast-iron segments. Nothing, therefore, is to be feared on the score of excessive pumping power being required; neither would there be any practical difficulty in drawing coals from the utmost depth to which we should have to descend. Steel wire ropes tapering in thickness towards the downward end, would not be overstrained by their own weight added to the usual load, and even if the depth were carried to such an extreme as to render the strain on the rope due to its weight a serious difficulty, the alternative of drawing at two stages could be adopted.

With regard to explosive gas it might have been anticipated that the greater superincumbent weight upon deep coal would cause more gas to exude, and thereby render the workings more fiery, but this does not appear to be the case. On the contrary, the evidence given before the committee on this point was to the effect that the evolution of gas appeared generally to diminish with increase of depth. In short, the only cause which it is necessary to consider as limiting the practicable depth of working, is the increase of temperature which accompanies increase of depth. The rate of this increase of temperature is about 1° F. for every 60 feet in depth, starting from 50 feet from the surface, where the temperature is in this country 50° at all seasons. The questions involved in this increase of temperature are, at what depth would the air become so heated as to be incompatible with human labour, and what means could be adopted to reduce the temperature of the air in contact with the heated strata. A great deal of interesting evidence was heard by the Commission as to the limit of human endurance of high temperature. The natural temperature of the human body, or rather of the blood which circulates through it, is 98°. A higher temperature is the condition of fever, and the maximum of fever heat appears to be about 105°. Labour appears to be impossible, except for very short intervals when the external conditions are such as to increase materially the normal temperature of the blood. The temperature of the air may be considerably in excess of 98° without unduly heating the blood, provided the air be very dry, because the rapid evaporation which then takes place from the body keeps down the internal temperature; but if the air be humid, this counter-action does not take place, or not in a sufficient degree, and then the blood absorbs heat from the surrounding medium and the condition of fever sets in. Now, in a coal mine, the air is never very dry, and is often very moist, and we must, therefore, regard a temperature of 98° in a coal mine as the extreme limit that could be endured by men performing the work of miners. For my part, I believe this temperature is beyond the limit of possible continuous labour in a mine, and most persons familiar with the interior of coal mines will agree with me in thinking that even 90° would prove a very distressing temperature, and one which would render the cost of labour much greater than usual. However, granting the practicability of working in a coal mine in an atmosphere at 98°, the next question is, what depth would involve that temperature of the air? The depth at which the earth would exhibit a temperature of 98° would be about 3,000 feet, but it is a different question at what depth the air circulating through the mine would acquire that temperature. The air being cold when it enters the workings at the bottom of the shaft, absorbs heat with great avidity from the surfaces of the passages through which it flows. As it travels along it continues to absorb heat, but less rapidly as its own temperature increases. The rate of absorption is complicated by the superficial cooling of the passages by the contact of the air. This cooling action is necessarily greatest near the shaft, where the air is coldest, and diminishes by increase of distance, so that both the air, and surfaces against which it sweeps, become hotter as the length of the air-course is increased. The progress towards complete assimilation of temperature is much slower in the permanent air courses than at the working face of the coal, because the coal at the face being newly exposed is hotter, and therefore communicates heat more readily to the air. In any case, however, the air will eventually acquire the heat due to the depth, if its contact with the strata be sufficiently prolonged. It follows, therefore, that the temperature of the air in a mine depends on the extent of the workings as well as on the depth of the pit. But great depth involves extensive workings, because the cost of the sinking could only be repaid by working a large area of coal. Extremely deep mines will consequently possess *both* the conditions tending to produce a high temperature of the air, and unless those conditions can be counteracted by some artificial expedient, the air would acquire the temperature of 98°, assumed to be the limit of practicable labour at a depth not greatly exceeding 3,000 feet.

It is a common idea that increase of temperature may be kept down to any extent by increase of ventilation, but this opinion will not bear examination. In the first place it requires an extravagant increase of motive power to accelerate the velocity of the current of air in any considerable degree, because the resistance increases in a ratio somewhat exceeding the cube of the velocity. In fact, the only way of materially increasing the volume of air is by enlarging the sectional area of the shafts and air-courses, which would be attended both with difficulty and expense. Assuming, however, that it would be generally practicable to effect a large increase of ventilation under the conditions incident to extremely deep mining, it is necessary to consider what would be the cooling effect realised by so doing. This is a very complex question, because the reduction of temperature in the air increases the emission of heat from the strata, and because the rate of absorption is affected, not only by difference of temperature, but also by the velocity of the current.

The uncertainty on the question of the power of air to absorb heat when flowing at different velocities and in different volumes through heated air-courses, and the difficulty of reasoning out any conclusion upon the subject led me to make, for the guidance of the committee, a series of experiments in which air was forced, in varying quantities, through pipes of different lengths and sizes, immersed in hot water, the temperatures being observed at the point of emergence. In these experiments the pipes were regarded as representing, on a small scale, the air-courses of a deep mine; the hot water being the equivalent of the heated strata through which the air would be conveyed. The particulars of these experiments will be found in the appendix to the evidence taken by the committee, and the results are embodied in tables, illustrated by diagrams, which show the progressive heating of the air as it travels along the passages, and exhibit the reductions of temperature effected by successive increments of the volume of air. From these tables and diagrams it will be seen that, with short pipes, representing short distances from the shaft, increased circulation has considerable effect in lowering temperature; but with pipes representing long distances from the shaft, the cooling effect of increasing the volume of air becomes insignificant. The conclusion to which the committee came, as to the depth at which coal could be worked, is expressed in the following words:—"The depth at which the temperature of the earth would amount to 98° would be about 3000 ft. Under the long-wall system of working a difference of about 7° appears to exist between the temperature of the air and of the strata at the working faces; and this difference represents a further depth of 420 ft., so that the depth at which the temperature of the air would, under present conditions, become equal to the heat of the blood, would be about 3,420 ft. Beyond this point the considerations affecting increase of depth become so speculative, that the committee must leave the question in uncertainty; but they consider that it may be fairly assumed that a depth of at least 4,000 ft. could be reached."

The committee decline to deal with hypothetical expedients for overcoming the difficulties, but they recognised the possibility of future discovery and experience counteracting, in some unknown degree, the effects of heat and humidity in restricting the

depth of working. It will, therefore, be for mining and mechanical engineers to bring all the resources of their science to bear upon this difficult problem of counteracting terrestrial heat, at depths where it approaches the limit of human endurance. The Commissioners adopting 4,000 ft. as the probable limit of practicable depth, came to the conclusion that there exists in this kingdom an aggregate quantity of about 146,480 millions of tons of available coal. If we assume that the future population of this country will remain constant, and that the consumption for domestic and manufacturing purposes, including exportation, will continue uniform at the present quantity, or merely vary from year to year without advancing, then our stock of coal would represent a consumption of 1,273 years. But if, on the other hand, we assume that population and consumption will go on increasing at the rate exhibited by the statistics of the last fifteen years, or, I might probably say, of the last fifty years, had accurate statistics been so long recorded, then the whole quantity of coal would, as shown by Mr. Jevons, be exhausted in the short space of 110 years. It will be generally admitted that the truth is likely to lie between these two extremes. The Commissioners refrained from expressing an opinion as to what the period of duration would actually be, but they presented certain alternative views of the question, resulting in periods varying from 276 to 360 years. But, all these estimates of duration have reference to the time required for absolute exhaustion of available coal, and leave untouched the important question of how long we are likely to go on before we become a coal-importing instead of a coal-exporting country. The computation of quantities made by the Commissioners, includes all coal seams exceeding 1 ft. in thickness, whatever the quality may be, and it is obvious that vast quantities of such coal can never be worked, except at a price which would render it more advantageous to purchase coal from abroad than to work it from such unfavourable beds. If, at the present time, while working our best and most available coal, our markets will barely exclude the coal of Belgium, what will be our position when driven to inferior coal more costly to work? If we look to cheaper labour for enabling us to work less valuable coal, I fear we shall look in vain; but there is one hope for a longer endurance of our prosperity as dependent on our coal, and that hope rests on the skill and perseverance of mining and mechanical engineers, who, even now, are called upon to lessen, by all the resources of mechanical science, the amount of human labour required in coal mines.

SCIENTIFIC SERIALS

THE *Monthly Microscopical Journal*.—The first paper is one of Mr. Parker's excellent studies, being on the osteology of the head of the sparrow-hawk. The first paragraph contains a generalisation which will surprise many ornithologists, for the Cariama is included among the raptorial birds; is this a result of the study of the skull? The accompanying drawings are excellent.—Dr. Royston-Piggott gives two articels, "On an Aërial Stage Micrometer," and "On the Spherules which compose the Ribs of the Scales of the Red Admiral Butterfly, and the Lepissna Saccharina."—An ingenious method of obtaining an equal illumination in both tubes of a binocular is contributed by Mr. W. R. Bridgman; and Mr Stewart endeavours to prove that the hair follicles of the negro's scalp are curved instead of straight; he also describes clearly the framework of the sucking feet of the Echinus.—These papers are followed by abstracts of interest, including several from the American journal, the *Lens*.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Feb. 6.—"Memoir on the Osteology of Hyopotamidæ," by Dr. W. Kowalevsky. The paper is intended to fill a deficiency in our knowledge of the extinct creation by giving a complete osteology of one family of the Paridigitate Ungulate. It has been supposed that fossil representatives of this family would exhibit a less reduced skeleton and a more complete number of digits than recent genera; yet such is not the case. The genera *Anoplotherium* and *Liphodon* present in their feet the same degree of reduction as in recent Ruminants, save the confluence in a canon-bone. Notwithstanding this, they have been considered the progenitors of the Ruminantia, from a deficiency in other forms. The present paper introduces a new form, known only by the teeth till now; these, the *Hyopotamidæ*, vary considerably in specific and generic form, ranging from the Lower Eocene up to the Lower Miocene period, and in size from a rabbit to a hippopotamus. The Eocene species, except one termed *diplopus*, have not lost the lateral digits, and are included in the genus *Hyopotamus*. The division of the Ungulata into *Paridigitata* and *Imparidigitata* must have occurred about the cretaceous period, as shown by the diversity exhibited by both groups from the lowest Eocene. The former, the *Paridigitata*, split very anciently, perhaps in the chalk, into those with tubercular, and others with crescentic teeth. These groups, once separate, kept entirely apart, but frequently followed parallel lines of descent. Following these two divergent lines of descent, both groups culminate at the present time in such forms as *Phacochœrus* and *Dicotyles* for one group, and the *Bovidæ* for the other, links between these being absent. The Paridigitata with crescentic teeth will be termed *Par. selenodonta*, and those with tubercular *Par. bunodonta*. To the first group belong *Anoplotherium*, *Liphodon*, *Hyopotamus*, and others, together with the existing ruminants, whilst the second embraces the *Suina*, *Hippopotamina* and *Entelodon*. There is in some cases difficulty in deciding whether the teeth are tubercular or crescentic, the lobes being so thick.

It is important to find some osteological characters to confirm the above division, and the hand and foot from their variations suggested probable data. In tracing the Paridigitata in time, there is a marked tendency to the gradual reduction of the manus and pes, and an advantage to the individual apparently arises from the simplification. By comparison of all forms, a simple structure of the manus and pes may be obtained, such as was probably possessed by the common ancestor, and such a type is nearly retained by *Hippopotamus*, and was possessed by *Hyopotamus*. In none of these forms is the limb pentadactylate. Supposing the feet to be pentadactylate, the following is the disposition of the digits in the type:—The two outer digits (the fourth and fifth) are always supported by one bone, the unciform in the manus, and the cuboid in the pes; the three succeeding inner digits are supported each by a separated bone, the third, second and first cuneiform in the pes, and the os magnum, trapezoideum, and trapezium, in the manus. In the latter the third digit touches the unciform, and the second the magnum; the second digit of the pes touches the third cuneiform. The first digit being lost in all Ungulata, the trapezium and first cuneiform support the second digit.

Beginning with this type, which was probably exhibited by the progenitors of the Paridigitata, the reduction along both lines of descent may be followed, and in doing so a series of parallel modifications may be obtained, though it is found among the crescent-toothed line that the reduction is much more rapid than along the tubercular toothed. By reduction of the foot is meant that locomotion is carried on by the two middle toes instead of by the original four; and this seems to be an advantage to the organism, as it is exhibited by all descending lines of Ungulata. Going further into detail, it is found that both in Selenodont and Bunodont Paridigitata, a two-fold method of reduction of the manus and pes, a simple or *inadaptive*, and an elaborate or *adaptive* method is observed. In the first or *inadaptive* mode of reduction, the foot, whilst losing its lateral digits, acquires no better adaptation to altered circumstances of locomotion than is derived from the mere thickening of the remaining digits. The relation between the carpal and tarsal bones, and the remaining two metacarpal and metatarsals, remains unaltered, and the remaining digits do *not* enter into any modification by which they can receive more ample support from the carpal and tarsal bones, by taking the place formerly occupied by the reduced digits. *Anoplotherium*, *Liphodon*, and *Hyopotamus*, are examples of this method of reduction.

In the second or *adaptive* method of reduction, the middle digits grow larger and thicker than in the first mode; but while broadening transversely they do not adhere to the ancestral type, but tend to gain a support on *all* the bones of the carpus and tarsus, pushing the lateral digits to the side and thereby gaining a better and more complete support for the body. The lateral digits, being rendered useless, tend to disappear, and the remaining digits, being pressed from both sides by the carpal and tarsal bones, tend to coalesce to form the *canon* bone of recent ruminants, or of the hind foot of *Dicotyles*. In this, the *adaptive* method, modification keeps pace with inheritance, and examples of it may be seen in *Sus*, *Dicotyles*, *Hyæmoschus*, and the Ruminants.

All extinct Paridigitata follow the first or *inadaptive* mode of reduction, whilst all living genera follow the second. Did the former not become extinct because of their incapacity to adapt themselves to altered circumstances, and the latter survive from being able to adapt themselves more fully to those circumstances? From an examination of fossil remains, it is found that the Paridigitates, of the genus Hyopotamus, were Selenodonta of the *inadaptive* line of descent, inheritance in them being stronger than modification. Among the Bunodonta following the *inadaptive* method, the old representatives are but little known, *Listriodon* and *Elotherium* being the most certain, and the latter apparently didactylate.

Following the adaptive method, among the Selenodonta are *Chœrotherium*, *Palæochœrus*, and the Swine, and the culminating or most reduced stage is not yet reached among the *Suina*, but it is certainly the direction in which they tend. Among the Bunodonta there is great difficulty in tracing the line of descent whence originate the Ruminantia. From the existence of *Hyæmoschus* we may predict that they were originally tetradactylate, and there are many other intermediate conditions, as *Tragulus* and *Gelocus*.

"Magnetic Survey of Belgium in 1871." By Rev. S. J. Perry. The magnetic observations which furnished the results contained in this paper were made during the Autumn months of 1871.

The instruments used and the methods adopted were almost identical with those employed in previous magnetic surveys of France.

The dip was observed by Mr. W. Carlisle, magnetic assistant of Stonyhurst Observatory, and the rest of the observations were taken by the Rev. S. J. Perry.

This new series of determinations of the terrestrial magnetic elements was rendered the more necessary, as preceding observers had chosen very few stations in Belgium, and as the curvature of the isodynamics and isoclinals in Dr. Lamont's maps of Belgium, Holland, and North-west Germany, indicated a very considerable disturbing cause in the first-named country.

The values obtained in 1871 are a strong confirmation of the suspicions of irregularity, to which former observations had given rise. For although the lines of equal dip, declination, and horizontal force bear a sufficiently close resemblance to those of neighbouring countries, there is evidence of much disturbance; and when the valves of the dip and horizontal force are combined, the isodynamics show clearly that the coal-measures, which stretch completely across the south east portion of Belgium, exercise a strong disturbing influence. This local magnetism might be incapable of producing more than a decided curvature of the isodynamics of an extended tract of country; but when all the stations of observation are situated within narrow limits, the perturbation completely masks the normal direction of the lines.

The following is a complete list of the magnetic elements observed at the different stations, and reduced to the common epoch of January 1, 1872.

Station.	Declination.	Dip.	Horizontal force.	Intensity.

Zoological Society of London, February 4.—Professor Huxley, F.R.S., V.P., in the chair.—A letter was read from Mr. Henry W. Piers, late acting curator of the South African Museum, Capetown, containing remarks on a specimen of the *Chimæra australis*.—Mr. E. Blyth exhibited and made remarks on some Tiger Skins from India, Burmah and Siberia.—A communication was read from Mr. R. Meldola, containing remarks on a certain class of cases of variable protective colouring in insects.—A communication was read from Mr. G. Gulliver, F.R.S., containing a series of measurements of the Red Blood Corpuscles of various Batrachians.—A paper was read by Dr. A. Günther, F.R.S., containing an account of certain species of Reptiles and Batrachians, obtained by Dr. A. B. Meyer in Celebes and the Philippine Islands.—A communication was read from Mr. A. G. Butler, containing a monographic revision of the genera *Zephronia* and *Sphærotherium* of the sub-order Myriopoda, together with descriptions of some new species of these genera.—A communication was read from Mr. G. French Angus, containing descriptions of eight species of Land and Marine Shells from various localities.—Messrs. P. L. Sclater and Osbert Salvin read the sixth of a series of papers on Peruvian Birds, collected by Mr. H. Whitely, in the Andes of Peru. The present communication contained an account of eighty species, collected principally at Cosnipetz, in the province of Cuzco.—A communication was read from Mr. H. Whitely, containing notes on the Humming Birds collected and observed by him in the Andes of Peru.—A communication was read from Dr. J. E. Gray, F.R.S., on the genus *Ocadia*, which he considered should be referred to the family *Bataguridæ*.

Chemical Society, February 6.—Dr. Williamson, F.R.S., vice-president, in the chair.—A communication was made by Dr. H. E. Armstrong "On the action of Sodium on Aniline."—A paper on "Anthrapurpurine," by Mr. W. H. Perkin, was then read by the author. Anthrapurpurine is a colouring matter which accompanies alizarine in the crude "artificial alizarine," now so largely manufactured and employed in dyeing instead of madder. Like alizarine it is capable of imparting brilliant and fast colours to cloth mordanted with alumina or iron.—A paper was also read by Dr. C. R. A. Wright on "Isomerism in the terpene family of hydrocarbons." In it he gives an account of his experiments with oil of nutmegs and oil of orange-peel.

Anthropological Institute, Feb. 4.—Col. A. Lane Fox, vice-president, in the chair.—Mr. W. L. Distant read a paper on the inhabitants of Car Nicobar." The people of Car Nicobar are taller than the average Malay, and darker in the colour of the skin. Their faith in a good spirit is slight, and in an evil spirit, which is invested with a personality, is strong. Their honesty is so well known that traders at once deliver their stores on the promise of these islanders to pay the necessary number of cocoanuts in return; and the promise is always fulfilled. They take but one wife, and adultery is severely punished.—A paper by Mr. J. E. Calder was read on the extirpation of the native tribes of Tasmania." The author who had had the advantage of above forty years' experience of the Tasmanians, entered very fully into their physical and mental characteristics, habits, customs, and modes of warfare, and the causes which led to the rapid extinction of all the tribes. They were intelligent, capable of considerable culture, and showed every disposition to become civilised; but the abundant supply of food induced indolence, which, together with the sudden and violent change of habit from savage to civilised life was one of the chief causes of extinction. The chairman announced the appointment of a Committee of Psychological Research.

Entomological Society, January 27, Annual Meeting.—Professor Westwood, president, in the chair. Statement of treasurer's account for 1872 read, and report of council.—Professor Westwood was re-elected as president for 1873, Messrs. S. S. Saunders, G. H. Verrall, C. O. Waterhouse and J. J. Weir, new members of council; Mr. McLachlan as treasurer; Messrs. F. Grut and G. H. Verrall, secretaries, and Mr. E. W. Janson as librarian.— he president delivered an address on the progress of entomology during the past year.

Geologists' Association, Feb. 7.—The Rev. T. Wiltshire, M.A., the retiring president, in the chair.—Henry Woodward, F.G.S., was elected president for 1873; and Robert Etheridge, F.R.S., Prof. Morris, F.G.S., James Thorne, F.S.A., and the Rev. T. Wiltshire, M.A., vice-presidents. Messrs. W. Hislop, J. L. Lobley, and A. Bott were re-elected treasurer, honorary secretary, and honorary librarian respectively. The report for the year 1872 shows the association to be in a flourishing state, and was unanimously adopted.

MANCHESTER

Literary and Philosophical Society, Dec. 24, 1872.—The president, Dr. J. P. Joule, F.R.S., drew attention to the increasing number of cases of hydrophobia. There was every reason for believing that this dreadful disorder was communicated from one animal to another by a bite, and seldom, if ever, was spontaneously developed. Inasmuch therefore as the effects of a bite nearly always occurred within four months, it would only be necessary to isolate all dogs for that period in order to stamp out the disease. That was the opinion of Dr. Bardsley, whose elaborate paper will be found in the fourth volume of the Memoirs of the Society, and probably gave rise to the practice of confining dogs at certain periods of the year, which has unfortunately been rendered to a great extent nugatory in consequence of having been only partially adopted.

Jan. 7.—The president referred to the great loss which the Society had experienced by the death of one of its most distinguished honorary members, Dr. Rankine; called away in the prime of life, his loss is one of the most severe that could have befallen science.—Mr. William H. Johnson called attention to the action of sulphuric and hydrochloric acids on iron and steel. If after immersion for say ten minutes in either of these acids a piece of iron or steel be tested, its tensile strength and resistance to torsion will be found to have diminished. Exposure to the air for several days, or gentle heat will, however, completely restore its original strength. Prolonged immersion in acid has a tendency to produce a crystalline structure in even the best wrought iron.

SCALE $\frac{1}{18}$

January 21.—The president explained a simple apparatus by means of which a very high degree of rarefaction of air could be produced with much facility, and which might in some circumstances be found preferable to the common air-pump or even the Sprengel. It consists of a glass funnel *a* surmounting a globe *b*, from the lower part of which a tube *c* descends to a jar of mercury *d*. The tube *e*, in connection with the receiver to be exhausted, is furnished with a vulcanised india-rubber plug which fits into the neck of the funnel. In using the apparatus the stopcock *f* is shut and the funnel filled with mercury. Then by lifting the tube *e* with its plug, the mercury fills the globe *b* and the pipe *c*. The tube *e* is then replaced, and the stop-cock being opened, the mercury descends in *c*, emptying the globe. By returning the mercury into the funnel by means of a pump, or more simply, by lifting the jar *d*, the process is repeated until the requisite degree of rarefaction is produced.

PARIS

Academy of Sciences, Jan. 27.—M. de Quatrefages, president, in the chair.—M. A. Trecul read the second part of his paper on the carpellary theory of the Papaveraceæ. This portion of the paper treats of *Glaucium* and *Eschscholtzia*.—M. Boussingault read a note on alimentary substances preserved by cold. The author exposed several articles of food to a temperature of −20° for several hours in closed flasks; this was in 1865. The substances are now perfectly sound and free from putrefaction. —M. Th. Lestiboudois read the continuation of his paper on the structure of the *Heterogenæ*.—M. Marès read a note on the vine sickness characterised by Phylloxera. The paper was referred to the commission on that subject.—A letter from M. I. Pierreon the determination of the boiling point of liquid sulphurous anhydride was then read. The method consists in introducing a thermometer, through a pierced cork, into a thin tube containing the anhydride. Another hole in the cork holds an exit tube; the apparatus is then suspended in the air, the SO_2 begins to boil, and the thermometer is then read. —M. Faye presented M. Heis's "Atlas cœlestis novus," and made some quotations from it on the number of stars visible to the naked eye; the author can see many stars put down by other astronomers as of the 7th or 8th magnitude.—M. L. d'Henry read a paper on the use of the mono-chromatic sodium light in observing the tints of litmus in alcalimetry. The author finds that this reaction is much more easily seen by the yellow light.—M. Ch. Valson sent a note on the modulus of refrigerating power in saline solutions.—MM. C. Friedel and R. D. Silva sent a note on a new tertiary alcohol, &c.; M. H. Joulie a note on the commercial estimation of nitrates; and MM. Gayon one on the spontaneous alteration of eggs: the author finds the putrid eggs full of vibriones; he intends to seek for the origin of these bodies.—M. Gréyhant sent a note on the estimation of carbonic oxide combined with hæmoglobin.—M. F. Pisani sent a paper on the analysis of Jeffersonite from New Jersey, and on the analysis of Arite from Mount Ar (Basses Pyrénées).—M. S. Chautrain sent a paper on the reproduction of eyes in the crayfish. The author has cut out the eyes of the crustacean, and finds that they grow again in about eleven months.

DIARY

THURSDAY, FEBRUARY 13.

ROYAL SOCIETY, at 8.30.—On Curvature and Orthogonal Surfaces: Prof. Cayley.—On a New Relation between Heat and Electricity: Prof. Guthrie

SOCIETY OF ANTIQUARIES, at 8.30.—On a Brass Bowl of the 12th century: T. A. Gardiner.—On Early Deeds and Charters: R. H. Wood.

MATHEMATICAL SOCIETY, at 8.—On Systems of Linear Congruences: Prof. H. J. S. Smith.—Application of the Hodograph to the Solution of Problems on Projectiles: J. Macleod.

FRIDAY, FEBRUARY 14.

ASTRONOMICAL SOCIETY, at 8.—Anniversary.

ROYAL INSTITUTION, at 9.—On Recent Progress in Weather Knowledge: R. H. Scott.

QUEKETT CLUB, at 8.

SATURDAY, FEBRUARY 15.

ROYAL INSTITUTION, at 3.—Comparative Politics: Dr. E. A. Freeman.

SUNDAY, FEBRUARY 16.

SUNDAY LECTURE SOCIETY, at 4.—Pre-Historic Fortifications: Lawson Tait.

MONDAY, FEBRUARY 17.

LONDON INSTITUTION, at 4.—Physical Geography: Prof. Duncan.

ENTOMOLOGICAL SOCIETY, at 7.

ASIATIC SOCIETY, at 3.

COLLEGE OF SURGEONS, at 4.—Osteology and Dentition of Extinct Mammalia, with their Geological and Geographical Distribution, &c.: Prof. Flower (Hunterian Lectures)

TUESDAY, FEBRUARY 18.

ANTHROPOLOGICAL INSTITUTE, at 8.—Note on the Macas Indians: Sir John Lubbock, Bart.—On the Relation of the Parish Boundaries in the South East of England to Great Physical Features: William Topley.

ZOOLOGICAL SOCIETY, at 8.30.—Report on the Hydroida collected during the Expeditions of H.M.S. Porcupine: Prof. G. J. Allman.—On Ægithognathous Birds: W. K. Parker.—Notes on the Anatomy of the Binturong (*Arctictis binturong*): A. H. Garrod.

ROYAL INSTITUTION, at 3.—Forces and Motions of the Body: Prof. Rutherford.

WEDNESDAY, FEBRUARY 19.

SOCIETY OF ARTS, at 8.

METEOROLOGICAL SOCIETY, at 7.—Description of an Electrical Self-registrating Anemometer and Rain-gauge: Fenwick W. Stow.—On the Madras Cyclone of May 2, 1872: Capt. H. Toynbee.—On the Character of the Storm of August 21–23, 1868, over the British Isles: Capt. T. O. Watson. —On some Results of Meteorological Telegraphy: Robert H. Scott.

LONDON INSTITUTION, at 7.—Paper and Discussion.

COLLEGE OF SURGEONS, at 4.—Hunterian Lectures.

THE PRESERVATION OF OUR NATIONAL MONUMENTS

THE necessity of some measures being taken for the preservation of our national pre-historic monuments is constantly being forced upon public attention by the acts of destruction so frequently reported in the newspapers, and which, it would appear, the power of public opinion is by itself unable to prevent.

We have only to refer to any archæological work which treats of our cromlechs and dolmens, and other megalithic monuments, to see at once how fearfully many of them have been mutilated, if they have not been absolutely destroyed within the last century or two. The disappearance of the monolith near Kit's Coty House, which, though fallen in Stukeley's time, was still there to mark what was then known as "the general's grave;" the hopeless confusion into which the "Countless Stones," also near Aylesford, have been thrown; the cairns within the circle, known as Long Meg and her Daughters, which, since Camden's time, have vanished, while the Daughters appear to have been reduced in number from 77 to 68; the double row of immense stones near Shap, the destruction of which has been so great that a village has been almost entirely built out of their remains;—these are but a few examples of this kind culled at random from Fergusson's "Rude Stone Monuments."

It was, moreover, only last year that a portion of Avebury, a monument perhaps only second in importance to Stonehenge, was threatened, and was only saved for posterity by the public-spirited liberality of Sir John Lubbock, who purchased the site.

With barrows and earthworks the destruction has been equally rapid, though less noticed. We have, however, seen an expostulation in the *Times* on the subject of the vallum of an ancient circular camp being converted into bricks, and the threatened destruction of Cæsar's Camp at Wimbledon is still a matter of public interest.

It is, perhaps, rarely the case that these monuments are destroyed in a merely wilful manner; it is usually from economical motives. The barrows offer a mound of soil well adapted for being carted away to give a top dressing to some neighbouring field, and there is also the secondary advantage, that their site, after the removal of the mound, offers no impediment to the passage of the plough. The stones of the megalithic monuments offer supplies of material both for the purposes of building and the repair of the neighbouring roads. As it was with "the Egyptian mummies, which Cambyses or Time had spared and which Avarice now consumeth," so it is with these rude monuments of our forefathers. When the belief was strong that "Mizraim cured wounds," there was some excuse for "mummies becoming merchandise," and "Pharaoh being sold for balsams;" but to dress our fields with the sepulchral mounds of our predecessors, and to break up their monuments for the repair of our barns and roads, seems to us what Sir Thomas Browne would have stigmatised as a worse than "irrational ferity."

It is with a view to preventing such barbarisms that Sir John Lubbock has introduced a Bill in the present Session of Parliament, to make provision for the preservation of certain national monuments, which has now been read a first time. The means adopted for dealing with this somewhat difficult subject appear to us well calculated for producing the desired result, and in a manner which even those who consider they have a right to destroy any monuments on their own property, cannot but regard as equitable.

The conservation of monuments such as barrows, dolmens, menhirs, earthworks, stone-circles, &c., is placed by the Bill under the charge of a body of Commissioners, consisting of the Inclosure Commissioners, the Master of the Rolls, the Presidents of the Societies of Antiquaries of London and of Scotland, the Keeper of the British Antiquities at the British Museum, and three other Commissioners to be nominated by the Crown. Under their charge are placed certain monuments specified in a Schedule attached to the Bill; but, with the consent of the Treasury, other monuments of a similar kind may, at any future time, be brought under their control. When once this has been done, any injury or damage to the monuments will be treated as a malicious injury and become penal, unless the written permission of the Commissioners has been obtained, or they have declined to purchase either the monument itself, or a power to restrain the owner or occupier of it from injuring it during a certain period of years.

Powers are given to the Commissioners to purchase the freehold, or other estate, in any monument and rights of way for the public to it, as well as to exercise the power of restraint from injury. The amount of compensation to be awarded under either head is to be determined under the provisions of an already existing Act of Parliament; but in all cases the consent of the Treasury will be necessary before there can be any outlay of public money.

These are the main provisions of the Bill, but the necessary clauses with regard to notices, powers of access, conservation of monuments, and other matters, have not been omitted, and have evidently been carefully considered. The Schedule attached to the Bill is at present apparently undergoing revision, but about eighty of the principal prehistoric monuments of the United Kingdom are already specified.

It appears to us that it would be wise for the local societies in our different counties to furnish Sir John Lubbock with catalogues of the principal monuments in their respective districts, such as in their opinion ought to be placed under the protection of the Commissioners, so as to make the list as complete in the first instance as possible, and avoid the necessity of making continual additions to it.

The mere fact of a barrow, dolmen, or camp, being thought of sufficient importance to be cited by name in an Act of Parliament would tend to raise it in the respect of the inhabitants of the surrounding country, and in most cases suffice to preserve it from wanton injury. The general spread of education will also do much to encourage a regard for our national antiquities, of which, notwithstanding neglect in the past, we have still a fair number to show. Let us do what we can to preserve them ere it be too late, and not let posterity charge the present generation with neglect, should at some future time a greater interest arise in these relics of a dim past, and it then be

found that of monuments now extant all that can be said will be "Etiam periere ruinæ."

In France it is certainly the case that where a building or other ancient structure is "classé comme monument historique," it is regarded with some degree of pride and affection by those who live near it, and the necessary expenses for the preservation of such monuments do not appear to be grudged.

In this country, also, what small expense the Treasury might incur in the defence and preservation of our national monuments would, we are sure, be cheerfully met; but we are inclined to think that it will only be in rare and exceptional cases that any outlay whatever, beyond, perhaps, the expense of a few notices, will be necessary.

Among the multitude of private Bills brought in at the commencement of a Session, it is not always that the doctrine of the "survival of the fittest" applies. In this instance, however, we trust that the Bill will be exposed to neither neglect nor mishap. It is supported by members on both sides of the House; it does not appeal to Party, but to the patriotism of the whole nation, and it is brought in under the auspices of a member whose reputation as an archæologist, though great throughout the country, is exceeded by his popularity as the author of the most successful measure of private legislation in modern times—the Bank Holiday Act.

HERBERT SPENCER'S PSYCHOLOGY

The Principles of Psychology. By Herbert Spencer. Second Edition. (London: Williams and Norgate.)

I.

To give readers some idea of the contents of a good book is very often the most useful thing a reviewer can do. Unfortunately that course is not open to us in the present instance. The subject is too vast. We cannot exhibit the grandeur; we can only in a few general phrases express our admiration of the profound, all-embracing philosophy of which the work before us is an instalment. The doctrine of evolution when taken up by Mr. Spencer was little more than a crotchet. He has made it the idea of the age. In its presence other systems of philosophy are hushed, they cease their strife and become its servants, while all the sciences do it homage. The place that the doctrine of evolution has secured in the minds of those who think for the educated public may be indicated by a few names taken just as they occur. Mr. Darwin's works, the novels of George Eliot, Mr. Tylor's "Primitive Culture," Dr. Bastian's "Beginnings of Life," and Mr. Bagehot's "Physics and Politics," have almost nothing in common but the idea of evolution, with which they are all more or less imbued. In a word we have but one other thinker with whom in point of influence on the higher thought of this, and probably of several succeeding generations, Mr. Spencer can be classed:—it does not need saying that that other is Mr. J. S. Mill.

As we cannot present such an outline of Mr. Spencer's system of psychology as would make it generally intelligible, the purpose of directing attention to the work will perhaps be best served by selecting as the subject of remark one or two points to which the presence of the controversial element may lend a special interest. After pointing out that the cardinal fact brought to light when nervous action is looked at entirely from the objective point of view, is, that the amount and heterogeneity of motion exhibited by the various living creatures, are greater or less in proportion to the development of the nervous system, Mr. Spencer comes to the vexed question of the relation between nervous phenomena and phenomena of consciousness. This is a subject about which in its more subtle aspects there is much uncertainty and some confusion of thought. It may be taken as established that every mode of consciousness is a concomitant of some nervous change. Given certain physical conditions accompanied by a special state of consciousness, and there is every reason to believe that physical conditions in every respect identical, will always be attended by a similar state of consciousness. This, and not more than this, we think, was intended by Mr. Spencer in his chapter on Æstho-physiology. Nevertheless, several able men have, it would appear, been led to suppose that he countenances a kind of materialism (not using the word to imply anything objectionable, for why not be materialists, if materialism be truth?), which forms no part of his philosophy. To give precision and emphasis to what we say, we would take the liberty to refer to the position taken up by Dr. Bastian in his remarkably able and important work on the "Beginnings of Life." The expression that definitely raises the issue of which we wish to speak, and which at the same time fixes Dr. Bastian to a view not in harmony with the teaching of Mr. Spencer, is the following:—"We have not yet been able to show that there is evolved, during brain action, an amount of heat, or other mode of physical energy, less than there would have been had not the Sensations been felt and the Thoughts thought;" but he believes that this is the case. Our present object is not so much to show that here speculation has got on a wrong track, as that, if we understand Mr. Spencer, it is not his opinion that anything of this kind takes place; though certainly some ambiguous phrases might be held to convey this meaning. We have mentioned the significant fact that the size of the nervous system holds a pretty constant relation to the amount and heterogeneity of motion generated. The implication is that none of the motion evolved during nervous action disappears from the object world, passes into consciousness in the same sense that physicists speak of momentum passing into heat; that whether consciousness arise or not, there will be for the molecular motion set up in the nerve substance, exactly the same mechanical equivalents. Whether, for example, those ganglia that in the body of each one of us are employed in carrying on what we call reflex action, are so many distinct seats of consciousness, like so many separate animals, an idea for which much has been said, or whether the nerve-changes that go on in these ganglia have no subjective side; in either case the objective facts will remain the same. If consciousness is evolved, it is not at the expense of a single oscillation of a molecule disappearing from the object world. No doubt it is hard to conceive consciousness arising in this apparently self-created way; but if any suppose that by using phrases that would assimilate mind to motion they ease the difficulty, they but delude themselves. It is as easy to think of consciousness arising out of nothing, if they will, as to

conceive it as manufactured out of motion; that is to say, the one and the other proposition are alike absolutely unthinkable. On this point Mr. Spencer writes, "Can we think of the subjective and objective activities as the same? Can the oscillations of a molecule be presented in consciousness side by side with a nervous shock, and the two be recognised as one? No effort enables us to assimilate them. That a unit of feeling has nothing in common with a unit of motion, becomes more than ever manifest when we bring the two into juxtaposition." Mr. Spencer's idea is that feeling and nervous action are two faces of the same ontological something,—a view that prohibits the notion of the one passing into or being expended in producing the other. The conclusion is that the transformations of physical energy remain unaffected by the presence or absence of consciousness.

Psychology has as yet been made a serious study by only a few individuals. Accordingly it is only the more striking and easily grasped peculiarities of Mr. Spencer's system that can be referred to with advantage. Of these the most imposing, and the one of which the educated public have already a slight second-hand acquaintance, is the doctrine that the brain and nervous system is an organised register of the experiences of past generations, that consequently the intelligence and character of individuals and of races depend much more on this, on the experiences of their ancestors, than on their individual experiences. The flood of light thrown by this conception on so many things previously dark and unfathomable, its power of bringing about harmony where before there was nothing but confusion and unsatisfactory wrangling, ought to have been sufficient to have secured it a universally favourable reception. This, however, has not been the case, and partly, perhaps, because of the very merits that recommend it. It may be that veterans who have won their laurels on, say, the battle-field of innate ideas, love the old controversy, and are not anxious to learn that both sides were right and both wrong. Moreover, it is the misfortune of this important addition to psychology, that it shows that previous workers in this field of inquiry nave at times been labouring in the dark to solve problems like in kind with the famous difficulty of accounting for the supposed fact, that the weight of a vessel of water is not increased by the addition of a live fish. For instance, should Mr. Spencer be right, the celebrated theory of the Will, elaborated by Prof. Bain, the able representative of the individual-experience psychology, becomes a highly ingenious account of what does not happen. Thus, the new doctrine can be accepted only at the expense of giving up much of what has hitherto passed for mental science.

The following sentences will serve to indicate Mr. Spencer's position: "The ability to co-ordinate impressions, and to perform the appropriate actions, always implies the pre-existence of certain nerves arranged in a certain way. What is the meaning of the human brain? It is that the many *established* relations among its parts stand for so many *established* relations among the psychical changes. Each of the constant connections among the fibres of the cerebral masses, answers to some constant connection of phenomena in the experiences of the race." "Those who contend that knowledge results wholly from the experiences of the individual, ignoring as they do the mental evolution which accompanies the autogenous development of the nervous system, fall into an error as great as if they were to ascribe all bodily growth and structure to exercise, forgetting the innate tendency to assume the adult form." "The doctrine that all the desires, all the sentiments, are generated by the experiences of the individual, is so glaringly at variance with facts, that I cannot but wonder how anyone should ever have entertained it." The circumstances which account for the existence of the individual-experience psychology, and which enable it still to hold out as a rival of the more advanced form that Mr. Spencer has given to the science are these: (1) the immaturity of the human infant at birth; (2) the lack of precise knowledge with regard to the mental peculiarities of the lower animals; (3) the still popular notion that the human mind does not resemble the mental constitution of the animals, that it is of a different order. Of course this last is now-a-days little more than a popular superstition, nevertheless it can be taken advantage of; and an argument to the effect that the mental operations of the animals are, to all appearance, so very different from the workings of the human mind, that they can supply nothing more than a worthless, if not a misleading analogy, has a very specious and scientific look about it, in the eyes of those who are not very well acquainted with the subject. Our ignorance of animal psychology may be still more boldly drawn on in defence of the theory under consideration. With a hyper-scientific caution, its advocates refuse to take into account anything (incompatible with their theory) concerning any one species of animal that has not been proved by a very overwhelmingly large number of very accurate observations. And they find it possible to maintain that it still remains unproved that any species of animal possesses either knowledge or skill not wholly acquired by each individual. A better acquaintance with the mental peculiarities of the animals is certainly a desideratum, and we hope that this rich field of investigation will not long remain uncultivated. In *Macmillan's Magazine* for this month there is an account of a series of observations and experiments on young animals by the present writer, which, unless they can be discredited, may reasonably be expected to go far to establish the fact of instinct, the fact of innate knowledge and unacquired skill; in other words, the phenomena on which the experience-psychology, minus the doctrine of inheritance, can throw no light whatever. Now, had not Mr. Darwin banished from every scientific mind the hypothesis of the miraculous creation of each distinct species of animal just as we see it, with all its strange organs and, to most people, still stranger instincts, the presumption against a system of human psychology that not only can give no account of the most striking phenomena in the mental life of the animals, but which strongly inclines those who hold it to pronounce such phenomena incredible, might not have been so apparent. But in the present state of our scientific knowledge, such a psychology, professing to be a complete system, is self-condemned. In its fundamental principles the science of mind must be the same for all living creatures. Further, if man be, as is now believed, but the highest, the last, the most complex product of evolution, a system professing to be an analysis and exposition of his mind, yet confessing itself in-

competent to deal with the necessarily simpler mental processes of lower creatures, must surely feel itself in an uncomfortably anomalous position.

It is, however, on the first-mentioned circumstance, the immaturity of the infant at birth, that most stress can be laid. The newly-born babe cannot raise its hand to its mouth, and doubtless for a long time after birth it has no consciousness of the axiom "things that are equal to the same thing are equal to one another." The helplessness of infancy is pointed to as furnishing ocular demonstration of the doctrine that, whatever may be the case with the animals, all human knowledge, all human ability to perform useful actions, must be wholly the result of associations formed in the life-history of each individual. But it can surely require little argument to show that this is an entirely unwarranted assumption. It might as well be maintained that because a child is born without teeth and without hair, the subsequent appearance of these must be referred wholly to the operation of external forces. Of the several lines of argument that might here be employed, let us, for the sake of freshness, take the analogy from the lower animals. We are not aware that it can be asserted as the result of prearranged and careful observations, that any creature at the instant of birth exhibits any of the higher instincts. A number of isolated and more or less accidental observations have been recorded; and apparently on the strength of these Mr. Spencer has made the following unqualified statement:—"A chick, immediately it comes out of the egg, not only balances itself and runs about, but picks up fragments of food, thus showing us that it can adjust its muscular movements in a way appropriate for grasping an object in a position that is accurately perceived." The fact is, that on emerging from the shell, the chick can no more do anything of all this than can the new-born child run about and gather blackberries. But between the two there is this great difference, that whereas the chick can pick about perfectly in less than twenty-four hours, the child is not similarly master of its movements in as many months. Our present point is, that it can be shown by experiment that the performances of the chick a day old, which involve the perceptions of distance and direction by the eye and the ear, and of many other qualities of external things, are not in any degree the results of its individual experiences. Let it now be remembered that, in the absence of conclusive evidence to the contrary, it has been considered a safe position to hold that the early knowledge and intelligent action of the chicken "may be, after all, nothing more than very rapid acquisitions, the result of that experimentation, prompted by the inborn or spontaneous activity." May we now, on the other side, similarly presume, until the contrary is shown, that the more tardy progress of the infant is not because its mental constitution has to be built up from the foundation out of the primitive elements of consciousness, which the chicken's has not, but rather because the child comes into the world in a state of greater physical, and therefore mental immaturity? The progress of the infant, however, has been so continually spoken of as if it were a visible process of unaided acquisition, that it may give some surprise when it is asserted from the other side that we have no sufficiently accurate acquaintance with the alleged acquisitions of infancy to justify the doctrine that they are different in kind from the unfolding of the inherited instincts of the chicken. To give definiteness to the attitude taken up, we would say, for example, that the facts concerning the early movements of the two lambs and the calf observed by Prof. Bain, and which, looked at from his point of view, were strong confirmation of the doctrine of individual acquisition, may be just as readily interpreted as the unfolding of inherited powers; which, as far as we know, start into perfect action at the moment of birth, in no single instance. From observations on several newly-dropped calves, the facts corresponding substantially with those recorded by Prof. Bain, the present writer could draw no conclusive evidence in favour of either the one theory or the other. One observation, however, may here be mentioned that seemed rather to favour the doctrine of inheritance. A calf one hour old, which had been staggering about on its legs for ten minutes, stepped out at the open door of the byre. It no sooner found itself in the open air, than it began to frisk and dance; it was left entirely to itself, and when it had been on its legs fifteen minutes, it—apparently in obedience to the feeling of fatigue—deliberately lay down, folding in its limbs after the established manner of its kind. This is all we know about calves; about children we know nothing at all. And it may fairly be asked how, when called in question, the assumption that underlies such statements as the following can be made good. We quote from Prof. Bain's account of the growth of voluntary power. He says:—"The infant is unable to masticate; a morsel put into its mouth at first usually tumbles out. But if there occur spontaneous movements of the tongue, mouth, or jaw, giving birth to a strong relish, these movements are sustained, and begin to be associated with the sensations; so that after a time there grows up a firm connection.' Bearing in mind that when born the child has no occasion for the power of masticating solid food; that the ability to suck, which involves an equally complex series of muscular adjustments, is what it requires, and this it has by instinct; bearing all this in mind, the question is, why may not the innate ability to masticate be developed by the time it is required quite as spontaneously as the teeth used in the operation? Take a parallel. The feeble nestling when it leaves the shell is blind. One of the several very pronounced and interesting instincts it exhibits at this stage is, that in response to certain sounds it opens its mouth and struggles to hold up its head to be fed. Several weeks later it begins to pick for itself. Now we put the question, is this second mode of filling its stomach to be considered a pure acquisition, while its original plan must certainly be regarded as pure instinct? No one, we think, will venture to answer in the affirmative; the more so as this is a case that may any day be put to the test of experiment. Where, then, is the evidence that the analogous progress from drawing milk to masticating solid food is of a different kind?

DOUGLAS A. SPALDING

OUR BOOK SHELF

Beiträge zur Biologie der Pflanzen. Herausgegeben von Dr. Ferdinand Cohn. Zweites Heft: (Breslau, 1872.)

THIS part contains the following memoirs:—Dr. Ciesielski, "Investigations on the downward Curvature

of the Root." Dr. Frank "On the position and direction of floating and submersed parts of plants." Dr. Cohn "On Parasitic Algæ." Dr. Schroeter "On certain Pigments formed by the Bacteriæ," and Dr. Cohn's "Investigations on Bacteriæ."

This work—Cohn's "Beiträge zur Biologie der Pflanzen"—is the organ more especially of the workers in the phyto-physiological laboratory at Breslau, under the guidance of the eminent Professor of Botany in the University there. The first part appeared in 1870 (NATURE, vol. iii. p. 242).

Dr. Ciesielski's researches follow up the interesting inquiries into the same subject opened a few years ago by Prof. Hofmeister and others. He sums up with the following propositions:—

1. The normal growth of germinating seedlings may be observed in a saturated atmosphere, if the albumen or cotyledons be kept constantly moist, without the root descending into either water or moist earth. The development of the root ceases however as soon as the reserve of nutrient matter in the seed is exhausted.

2. The longitudinal extension of the root takes place exclusively in a relatively narrow region behind the tip.

3. The downward curvature of the root takes place at that point where the longitudinal growth of its cells is at a maximum.

4. Gravitation occasions the downward curvature.

5. This curvature is not passive but active; that is to say, gravitation occasions in the root a tension of the tissue whenever it departs from its normal direction, and thus determines downward curvature.

6. This tension is due to the more considerable growth of those cells which lie on the side of the root turned towards the zenith.

7. The more marked growth of the cells of this side of the root is occasioned by the circumstance that the cell-contents of the upper side turned towards the zenith are much less concentrated than in the under side; which, again, is due to the action of gravity which determines that the more concentrated cell-sap, being the heavier, shall occupy the under side of the root.

8. If the outermost tip (*Vegetationskegel*) of a root be cut off, it may indeed elongate through mere extension of its tissues, but it is no more capable of downward curvature.

9. If however it afterwards developes a new formative apex, as occasionally happens, and so elongates at the cut apex, the root again becomes capable of downward curvature.

10. Centrifugal force determines in a similar manner and on analogous ground, the curvature of the root in the direction of this force, as does gravitation in that towards the nadir.

The next thing will be to explain the relation of *ascending* axes to gravitation. It would seem as though heliotropismus and geotropismus had squabbled over the embryo and compromised matters at last by each taking a *Vegetationskegel*, one of the plumule the other of the radicle, with its active future control!

Dr. Frank's paper is an inquiry into the causes which influence the position and direction of the floating and submersed leaves of aquatic plants apart from the direct operation of gravity and sunlight, which are not causes directly productive of special modifications of growth, but rather guides according to which the organ in the course of growth adjusts itself so far as it is able, until it has attained a position the most advantageous to it.

Prof. Cohn's memoir touches upon the question, of peculiar interest just now, of the relation of the lower forms of vegetable life destitute of chlorophyll to the organic matter in which they find their matrix and to the inorganic world, with regard to their power of assimilating independently their necessary nutriment and reducing carbonic acid. He also carefully describes as a new unicellular genus of truly parasitic algæ, *Chlorochytrium* (allied to *Hydrocytium* and the *Chytridinæ*) which he finds inhabiting the fronds of *Lemna trisulca*. The occurrence of this chlorophyll—containing alga in *Lemna*, he regards as presenting an analogy with the presence of the green gonidial layer in lichens, which he looks upon similarly as an endophytal alga.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

The Janssen-Lockyer Application of the Spectroscope

I SEE by a letter in the *English Mechanic and World of Science* of January 31, that Mr. R. A. Proctor claims for Dr. Huggins the credit of having publicly described in Feb. 1868, the method of viewing the solar protuberances without a total eclipse.

Permit me to state that to Mr. Lockyer undoubtedly belongs the credit of having known this method even before his preliminary paper in 1866 in which it was sufficiently published. We had numerous conversations on the subject, and when he showed me the MS. of his preliminary paper and told me at the same time that he was about to ask a grant for the purpose of procuring a more powerful spectroscope, I advised him to introduce his views in the shape of a question, which he accordingly did in the following terms:—"May not the spectroscope afford us evidence of the existence of the 'red flames' which total eclipses have revealed to us in the sun's atmosphere, although they escape all other methods of observation at other times? and if so may we not learn something from this of the recent outburst of the star in Corona?"

I gave this advice to my friend, Mr. Lockyer, because I thought that as it might be some time before he obtained the new instrument it might be well that he should publish what I conceived would enable him to claim for himself the knowledge of this principle. And I think that anyone well acquainted with spectra on reading the question put, could not fail to see what was meant, and if he were previously ignorant of the principle, he could not fail to perceive it. I therefore feel rather astonished that anyone should claim the statement made by Huggins two years afterwards as being the commencement of a new principle. The method founded upon this principle was first successfully applied by Messrs. Janssen and Lockyer, acting independently of each other, in the year 1868. Mr. Lockyer had by this time obtained his improved spectroscope, and the very first day he used it he made the discovery. I do not think there is any reason to suppose that Mr. Lockyer was at all aided, as was suggested by Mr. Huggins, in detecting these lines by the somewhat vague information of what had been done at the total eclipse in India. He was now provided with an instrument capable of showing these lines to a child—made in fact for the purpose of showing them. Now what would have been thought of any one of the Indian observers if during the few minutes of a total eclipse he had failed to detect the existence of bright lines? Can we imagine therefore that an intelligent observer like Mr. Lockyer, with an instrument constructed for the purpose and with unlimited time at his disposal, should have failed in detecting such lines even had he not previously been sure that they existed? I confess I cannot understand any observer failing in a thing of this nature, and therefore I do not know well how to account for the somewhat puzzling remark made by Dr. Huggins in his notes to Schellen's "Spectrum Analysis" as follows:—

"Though to Mr. Lockyer is due the first publication of the idea of the possibility of applying the spectroscope to observe the red flames in sunshine, as a matter of history it should not be passed over that, about the same time, the same idea occurred quite independently to two other astronomers, Mr. Stone of Greenwich, and Mr. Huggins. These observers were however unsuccessful in numerous attempts which they made to see the spectra of the prominences, for the reason probably that the spectroscope which they employed was not of sufficient dispersive power to make the bright lines of the solar flame easily visible. When the position of the lines was known, Huggins saw them instantly with the same spectroscope (two prisms of 60°), which he had previously used in vain."

I confess I cannot yet understand why a distinguished observer

like Dr. Huggins, possessing such an instrument as he did, should fail to have seen the bright lines at first, nor why, believing as he did in the aid afforded by the Indian observations to an observer searching for these lines, he should yet have left it to Mr. Lockyer to make this discovery.

BALFOUR STEWART

Dr. Bastian's Experiments on the Beginning of Life

IN the issue of NATURE for January 9, Dr. Burdon Sanderson has recorded some experiments on the behaviour of certain organic mixtures boiled for five or ten minutes in flasks which were hermetically sealed during ebullition. He found, as Dr. Bastian had done, that Bacteria appeared in these sealed vessels —not always, but frequently. Dr. Sanderson is, however, careful not to endorse the conclusions which Dr. Bastian has drawn from these experiments. This method of experimenting appears to me to involve two serious sources of error which invalidate them in so far as they are used to support the theory of spontaneous generation.

The first source of error is the possibility of the introduction of atmospheric germs at the moment of sealing.

Those who are practised in the sealing of flasks during ebullition are aware that the sealing can only take place just as ebullition is about to cease; otherwise the vessel bursts, or the imprisoned steam opens a path for itself through the softened glass where the flame is being applied. There is thus at the moment of sealing, a risk of some reflux of air into the flask and a consequent vitiating of the experiment. Perhaps it may be thought that because air thus introduced has to pass through the flame applied to the tube through the red-hot tube itself, and enters a flask whose contents are not far below the boiling temperature, any germs contained in it must be destroyed; but that is a very hazardous assumption. *Momentary* contact (or approximate contact) with a flame or a heated surface is by no means so destructive as at first appears, and experience has taught me to suspect that the contents of a boiling flask are not speedily deprived of vitality. This source of error is probably not a frequent occurrence in Dr. Bastian's experiments, but I am inclined to think that it was a frequent one in Dr. Wyman's experiments, and that it seriously vitiates all those experiments in which air passed through a heated tube was used. At any rate the exactness of experiments so conducted is very much at the mercy of the care and dexterity of the operator, and hence, probably, their contradictory results in different hands.

In repeating Dr. Bastian's experiments I have avoided this source of error by inserting a tight plug of cotton wool in the neck of the flask before beginning to boil. In this way any chance germs introduced by an accidental reflux of air during sealing are prevented from passing into the flask.

The second source of error is much more important. It is this:—*Dr. Bastian's process does not insure that the entire contents of the flask are effectively exposed to the boiling heat.* Herein lies, I believe, the chief cause of the inconstant and contradictory results obtained by him. It is beyond doubt that Dr. Bastian is perfectly correct in his statement that the experiments made by Pasteur with "Pasteur's solution," and by Lister with urine, yield different results when made with other solutions and mixtures. The contrast is most striking. In my own experiments I have found that filtered infusions of any animal or vegetable substances (and I have tried a very great variety) can be invariably preserved unchanged when boiled for five or ten minutes in a flask plugged with cotton wool; but if milk be treated in the same way, or if a few fragments of a green vegetable be added to the infusion, or if alkaline albuminous solutions or mixtures, containing cheese, be treated in the same way, they almost invariably breed Bacteria in abundance. What is the cause of this difference? For some time it appeared to me difficult to account for, but I came to the conclusion at length that it was simply due to the fact, that with the more complex organic mixtures every particle of the material within the flask does not really attain the boiling heat. These more complex mixtures generally froth excessively in boiling, and spurt about particles which adhere to the glass, and probably some of these escape the full effect of the heat. What first led me to this conclusion was the behaviour of milk. Milk boiled for ten or even twenty or thirty minutes, in a plugged flask, almost invariably curdled and produced Bacteria in a few days; but when the milk was put into a long-necked flask, plugged with cotton wool, and hermetically sealed, and the flask boiled in a good-sized can of water for twenty or thirty minutes, then the milk remained permanently unchanged, and produced no Bacteria. I possess specimens of milk treated in this way which have remained unchanged for many months, though exposed to warmth, to light, and free access of air, that is to say, to air filtered through a good plug of cotton wool. I obtained similar results with the other organic mixtures which could not be kept unchanged by simple boiling over the flame. Highly putrescent mixtures, containing blood-serum, egg-albumen, fragments of meat and vegetables, remained perfectly barren after the flask containing them had been immersed in a water-bath kept at a boiling heat for twenty or thirty minutes.

The essential conditions of the experiment are, first, the effective exposure of the whole contents of the flask to a boiling heat; secondly, the absolute prevention of any fresh entrance of extraneous solid or liquid particles; and the conclusion I have come to is that if these conditions are rigidly observed, the flasks remain barren; if they do not remain barren it is simply because one or other of these conditions has not been observed.

Manchester WM. ROBERTS

The unreasonable

I UNRESERVEDLY accept Prof. Clifford's disavowal of the meaning I attributed to his words concerning Kant's Antinomies, in his Address (*Macmillan's Magazine*, Oct. 1872). At the same time I cannot allow that the misprision was wholly due to my "exuberant imagination." He said, "The opinion . . . is set forth by Kant . . . in the form of his famous doctrine of the antinomies," &c. This ought to mean that the "doctrine of the antinomies" is one form of that "opinion;" and the opinion being, "that at the basis of the natural order there is something which we can know to be *unreasonable*," I was fully justified by the mere words of the Address in the inference (which he disclaims) that he intended to identify the doctrine of the antinomies (the Antithetic, in fact) with that of the unreasonable basis of the natural order. How was I to know that the "something" was either (? which) "the transcendental object" or the world of *noumena*?

I premise, then, that it is the Antithetic which "is set forth by Kant in his famous [but little understood] doctrine of the Antinomies," and *not* "the opinion that at the basis of the natural order there is something which we can know to be unreasonable." Prof. Clifford, however, meant to signalise the latter; and he asserts, and by sundry extracts from the *K. r. V.* attempts to substantiate the assertion, that "the transcendental object [which lies at the basis of the natural order] is *unreasonable*, or evades the processes of human thought."

Now Kant, so far from proving (or asserting) *that*, takes pains to show that it is *reasonable*, though it persistently seems to be the reverse! According to Kant, the thing *per se* illusorily appears to be the object of experience; and this illusion is inevitable, and no criticism can dispel it. (Kant compares it to the seeming magnitude of the horizontal moon.) But criticism can and does explain it, so that, though it persists as a spectre haunting the reason, it is wholly and strictly amenable to the processes of reason, or in Prof. Clifford's sense, *reasonable*.

Of Prof. Clifford's quotations, (*a*) and (*b*) are irrelevant to his second position; the former does not directly touch "the processes of human *thought*;" the latter does not touch "the transcendental object!" His third position is equally unsupported by the extract, "Man [*not* Mann] kann aber," &c., which may be thus rendered:—"But conversely we can also deduce from this antinomy a real, not indeed a dogmatical, but a critical and doctrinal advantage, namely, of indirectly showing the transcendental ideality of phenomena (*Erscheinungen*)." The method is by showing that the antithesis is contrary, as distinguished from contradictory, and by invalidating both the alternatives, whence it follows that the subject of them is not an existing totality. The antinomies are thus used, not as Prof. Clifford vainly imagines, to prove that the transcendental object is unreasonable, but that the postulate of its being a *noumenon*, or thing *per se*, or true basis of the natural order, is untrue, both alternatives being false.

Prof. Clifford is, as I said, really attacking Hamilton. I do not care where he got the doctrine from, nor what he does with it. If it amuses him to set up these absurd nine-pins and then bowl them over, with flourish of trumpets, I have no wish to interfere with him, only he had better mind his H's and K's, and not impute this stuff to Kant. Once for all: in Hamilton's

system the opposed propositions, which do show their subject to be unreasonable, are intended to do duty as contradictories. But in Kant's system the opposed propositions in an antinomy are only seeming contradictories, are virtually contraries, and their common subject remains the subject of an intelligible proposition, and one that Kant believes himself to have substantiated, after the contraries are invalidated: so that the subject is after all amenable to the processes of human thought, though not representing an object of experience. I dare not further trespass on the columns of NATURE to comment upon Prof. Clifford's views of the two legs of Kant's philosophy! Certainly the one leg is wholly due to my opponent's "exuberant imagination:" it is Hamilton's leg, not Kant's.

Athenæum Club, Feb. 17 C. M. INGLEBY

Inherited Feeling

THE remarkable case of an inherited feeling of dislike for a special class of persons, communicated by Mr. Darwin, appears to me to support a view I have long held (but not yet published) as to the explanation of another class of so-called instincts. The three separate instances given in which the dogs showed a violent antipathy to butchers, either without seeing them or when they were dressed as gentlemen, clearly indicates that it was through the sense of smell that the painful sensation was experienced; and this is quite in accordance with the wonderful delicacy and importance of this sense in most animals, and especially in dogs. It is natural to suppose that some ancestor of these dogs was systematically and cruelly ill-treated by several butchers, perhaps from some thievish propensity or other bad habit which required frequent punishment, so that the smell of a butcher came to be invariably associated with pain and a desire for revenge. But the most important fact to observe is, that there must be some peculiar odour developed in human beings by constant contact with flesh, which a dog can recognise apart from individual peculiarities and in spite of perfect disguise. Now the power many animals possess to find their way back over a road they have travelled blindfolded (shut up in a basket inside a coach for example) has generally been considered to be an undoubted case of true instinct. But it seems to me that an animal so circumstanced will have its attention necessarily active, owing to its desire to get out of its confinement, and that by means of its most acute and only available sense it will take note of the successive odours of the way, which will leave on its mind a series of images as distinct and prominent as those we should receive by the sense of sight. The recurrence of these odours in their proper inverse order—every house, ditch, field, and village having its own well-marked individuality—would make it an easy matter for the animal in question to follow the identical route back, however many turnings and cross-roads it may have followed. This explanation appears to me to cover almost all the well-authenticated cases of this kind.

ALFRED R. WALLACE

I AM able to corroborate the remarkable fact mentioned in Dr. Huggins's letter in your last.

My father possessed a mastiff, a son of Sybil, daughter of Turk, who has, ever since he was a pup, evinced the same antipathy to butchers. We have hitherto been unable to explain it, for he is always perfectly good tempered with other tradesmen who come to the house. The butchers have, on several occasions, tried to propitiate him by throwing him presents of meat, but although willingly enough received, it has done nothing towards abating his hostility. H. G. BROOKE

Hale Carr, Altrincham, Feb. 15

I HAVE a cat, of a long-haired breed, whose aversion to dogs is unusually strong. Last autumn, six kittens of hers, under two days old, were in a corner of the kitchen where they had had no opportunity of making acquaintance with any dog; yet, on being stroked (in their mother's absence) by a hand which a dog had just licked, more than one of them "swore" violently. This was repeated several times, but the little creatures showed no dislike to being touched with a clean hand.

A LOVER OF ANIMALS

Two or three months ago I was walking with my two little girls near the railway bridge at West Kensington, when the children (who always find the attraction of a fine dog irresistible) made me stop to admire a tall and remarkably handsome mastiff, apparently the property of a man who stood by with a hand-barrow. He was speaking to two other men of this dog, and of another of the same kind which he had at home, and telling them that they were quiet and amiable to all men but butchers, and that it was not safe for a butcher to come near either of them. One of the men said that he believed all dogs of that breed showed the same antipathy; and added that when they were left loose at night to guard premises, they would always allow a policeman to enter.

This chance conversation is perhaps hardly worth troubling you with, as I have no means of ascertaining whether these dogs claimed kindred with Turk, but I send it to you, nevertheless.

M.

Kensington Square, Feb. 17

*EFFECT OF LIGHT ON SELENIUM DURING THE PASSAGE OF AN ELECTRIC CURRENT.**

BEING desirous of obtaining a more suitable high resistance for use at the Shore Station in connection with my system of testing and signalling during the submersion of long submarine cables, I was induced to experiment with bars of selenium, a known metal of very high resistance. I obtained several bars varying in length from 5 to 10 centimetres, and of a diameter from 1 to $1\frac{1}{2}$ millimetres. Each bar was hermetically sealed in a glass tube, and a platinum wire projected from each end for the purpose of connection.

The early experiments did not place the selenium in a very favourable light for the purpose required, for although the resistance was all that could be desired—some of the bars giving 1,400 megs. absolute—yet there was a great discrepancy in the tests, and seldom did different operators obtain the same result. While investigating the cause of such great differences in the resistance of the bars, it was found that the resistance altered materially according to the intensity of light to which it was subjected. When the bars were fixed in a box with a sliding cover, so as to exclude all light, their resistance was at its highest, and remained very constant, fulfilling all the conditions necessary to my requirements; but immediately the cover of the box was removed, the conductivity increased from 15 to 100 per cent. according to the intensity of the light falling on the bar. Merely intercepting the light by passing the hand before an ordinary gas-burner placed several feet from the bar increased the resistance from 15 to 20 per cent. If the light be intercepted by rock salt or by glass of various colours, the resistance varies according to the amount of light passing through the glass.

To ensure that temperature was in no way affecting the experiments, one of the bars was placed in a trough of water so that there was about an inch of water for the light to pass through, but the results were the same; and when a strong light from the ignition of a narrow band of magnesium was held about nine inches above the water the resistance immediately fell more than two-thirds, returning to its normal condition immediately the light was extinguished.

PARTING BANQUET TO PROF. TYNDALL

ON the evening of February 4 Prof. Tyndall's visit to the United States was crowned by a banquet at Delmonico's, New York, at which there were present about 200 of the most distinguished citizens of the country, presided over by the Hon. William M. Evarts. Among the company present were the following:—The Rev. Dr. Bellows, Parke Godwin, Dr. Draper, A. M.

* Communicated to the Society of Telegraph Engineers, February 12, by Mr. Latimer Clark, from Mr. Willoughby Smith, Electrician to the Telegraph Construction Company.

Mayer, Rev. Henry Ward Beecher, President F. A. P. Barnard, Rev. Dr. Hitchcock, Rev. Dr. H. C. Potter, Dr. A. Flint, Dr. Hammond, Rev. Dr. Osgood, A. Appleton, G. S. Appleton, Judge Brady, Dr. H. Draper, V. Botta, J. C. Draper, Judge Daly, the Hon. E. D. Morgan, B. Silliman, Prof. G. F. Barker, of Yale College, Gen. Franklin, D. Van Nostrand, H. S. Kendrick, Prof. Chandler, Prof. S. F. Baird, of the Smithsonian Institute, Prof Michie, Prof. Pompelly, E. L. Godkin, Fred. Law Olmsted, Prof. W. H. Chandler, of Columbia College, Sterry Hunt, C. W. Field, Gen. Myers, E. L. Youmans, A. S. Hewitt, Wilson G. Hunt, Dr. Sims, Col. Dwight, J. B. Scribner, W. H. Appleton.

There were several very happy after-dinner speeches, by men of various professions and opinions. We present our readers with a few extracts from the speech of Prof. Tyndall.

Referring to the interest shown in his lectures, he said:—"Every such display of public sympathy must have its prelude, during which men's minds are prepared, a desire for knowledge created, an intelligent curiosity aroused. Then in the nick of time comes a person who, though but an accident, touches a spring which permits tendency to flow into fact, and public feeling to pass from the potential to the actual. The interest displayed has really been the work of years, and the chief merit rests with those who were wise enough to discern that, as regards physics, the detent might be removed, and the public sympathy for that department of science permitted to show itself. Among the foremost of those who saw this must be reckoned my indefatigable friend Prof. Youmans. In no other way can I account for my four months' experience in the United States. . . To no other country is the cultivation of science in its highest forms of more importance than to yours. In no other country would it exert a more benign and elevating influence. What, then, is to be done toward so desirable a consummation? Here I think you must take counsel of your leading scientific men, and they are not unlikely to recommend something of this kind. I think, as regards physical science, they are likely to assure you that it is not what I may call the statical element of buildings that you require so much as the dynamical element of brains. Making use as far as possible of existing institutions, let chairs be founded, sufficiently but not luxuriously endowed, which shall have original research for their main object and ambition. With such vital centres among you, all your establishments of education would feel their influence; without such centres even your primary instruction will never flourish as it ought. I would not, as a general rule, wholly sever tuition from investigation, but, as in the institution to which I belong, the one ought to be made subservient to the other. The Royal Institution gives lectures—indeed it lives in part by lectures, though mainly by the contributions of its members, and the bequests of its friends. But the main feature of its existence—a feature never lost sight of by its wise and honourable Board of Managers—is that it is a school of research and discovery. And though a by-law gives them the power to do so, for the twenty years during which I have been there no manager or member of the institution has ever interfered with my researches. It is this wise freedom, accompanied by a never-failing sympathy, extended to the great men who preceded me, that has given to the Royal Institution its imperishable renown.

"I have said that I could not wholly sever tuition from investigation, and I should like to add one word to this remark. In your chairs of investigation let such work as that in which I have been lately engaged be reduced to a minimum. Look jealously upon the man who is fond of wandering from his true vocation to appear on public platforms. The practice is absolutely destructive of original work of a high order. Now and then the discoverer, when he has anything important to tell, may appear with benefit to himself and the world. But as a general rule he must leave the work of public lecturing to others. This may appear to you a poor return for the plaudits with which my own efforts have been received; but these efforts had a special aim. My first duty toward you, moreover, is to be true, and what I say here is the inexorable truth.

"As to the source of the funds necessary for founding the chairs to which I have referred it is not for me to offer an opinion. Without raising the disputed question of State aid, in this country it is possible to do a great deal without it. As I said in my lectures, the willingness of American citizens to throw their fortunes into the cause of public education is without a parallel in my experience. Hitherto their efforts have been directed to the practical side of science, and this is why I sought in my lectures to show the dependence of practice upon principles. On the ground, then, of mere practical, material utility, pure science ought to be cultivated. But assuredly among your men of wealth there are those willing to listen to an appeal on higher grounds, to whom, as American citizens, it will be a pride to fashion American men so as to enable them to take their places among those great ones mentioned in my lectures. Into this plea I would pour all my strength. Not as a servant of Mammon do I ask you to take science to your hearts, but as the strengthener and enlightener of the mind of man.

"Might I now address a word or two to those who in the ardour of youth feel themselves drawn toward science as a vocation. They must, if possible, increase their fidelity to original research, prizing far more than the possession of wealth an honourable standing in science. They must, I think, be prepared at times to suffer a little for the sake of scientific righteousness, not refusing, should occasion demand it, to live low and lie hard to achieve the object of their lives. I do not here urge anything upon others that I should have been unwilling to do myself when young. Let me give you a line of personal history. In 1848, wishing to improve myself in science, I went to the University of Marburg—the same old town in which my great namesake, when even poorer than myself, published his translation of the Bible. I lodged in the plainest manner, in a street which, perhaps, bore an appropriate name while I dwelt upon it. It was called the *Ketzerbach*—the heretic's brook—from a little historic rivulet running through it. I wished to keep myself clean and hardy; so I purchased a cask and had it cut in two by a carpenter. Half that cask, filled with spring water over night, was placed in my small bedroom, and never during the years that I spent there, in winter or in summer, did the clock of the beautiful Elizabethekirche, which was close at hand, finish striking the hour of six in the morning before I was in my tub. For a good portion of the time I rose an hour and a half earlier than this, working by lamp-light at the differential calculus when the world was slumbering round me. And I risked this breach in my pursuits and this expenditure of time and money, not because I had any definite prospect of material profit in view, but because I thought the cultivation of the intellect important—because, moreover, I loved my work, and entertained the sure and certain hope that, armed with knowledge, one can successfully fight one's way through the world. It is with the view of giving others the chance that I then enjoyed that I propose to devote the surplus of the money which you have so generously poured in upon me, to the education of young philosophers in Germany. I ought not, for their sake, to omit one additional motive by which I was upheld at the time here referred to—that was a sense of duty. Every young man of high aims must, I think, have a spice of this principle within him. There are sure to be hours in his life when his outlook will be dark, his work difficult, and his intellectual future uncertain. Over such periods, when the stimulus of success is absent, he must be carried by his sense of duty. It may

not be so quick an incentive as glory, but it is a nobler one, and gives a tone to character which glory cannot impart. That unflinching devotion to work, without which no real eminence in science is now attainable, implies the writing at certain times of the stern resolve upon the student's character: 'I work not because I like to work, but because I ought to work.' In science, however, love and duty are sure to be rendered identical in the end."

*THE TROGLODYTES OF THE VEZERE**

I HAVE come to speak to you about the Troglodytes of the Vezère, of that fossil population whose subterranean dwellings we are about to visit.

Their existence dates back to a startling antiquity. We do not know their name; no historian has mentioned them, not a vestige of them had been discovered until the last eight years; and yet they are better known to us, in many respects, than certain nations celebrated in classical history. We know their mode of life, their industry, their arts, and all the details of their existence. Is not this the true history of races, a history far more interesting than that of their battles, their conquests, and even their dynasties? How can we know so much of a people who have left no trace in the memory of man, and whose very existence would have been declared impossible twenty years ago? Are they the creatures of a dream, like the celebrated Troglodytes of Montesquieu? No. Nothing is more real than our Troglodytes; nothing more authentic than their annals. In the caverns which they inhabited, in those in which they laid their dead, have been found fragments of their meals, productions of their industry and arts, and remains of their bones. It is in this book that their history has been read; it is with these documents that their past existence has been resuscitated.

Many *savants* have taken part in these researches. Among others, Christy, the Marquis de Vibraye, M. Falconer, and our two colleagues, MM. Louis Lartet and Elie Massénat, deserve honourable mention; but there is one name that eclipses all the others, it is that of the founder of human palæontology—Edward Lartet.

I.—*Determining the Epoch*

Before speaking about a people it is well to assign it a place in time. But in this instance ordinary chronology is inapplicable. We are touching on periods of an incalculable length. Since the epoch when our Troglodytes lived, the climate and fauna have undergone considerable modifications, which have been produced slowly, without any revolution, without violent action, under the influence of those imperceptible causes which are still at work in our own day; and when we consider that, during the course of centuries of known time, these causes have only produced scarcely appreciable changes in our surroundings, we can have some idea of the prodigious duration of what is styled a geological epoch. These immense periods can neither be measured by years, by centuries, nor by thousands of years; these dates cannot be expressed in numbers, but we can determine the order in which the geological epochs followed each other, and the periods of which each is composed. These are the dates of the history of our planet; and the elements of what Edward Lartet has designated *palæontological chronology*. It will suffice for us to determine our dates from the commencement of the *quaternary epoch*.

The end of the tertiary epoch had been signalised by a remarkable phenomenon, of which the cause is not yet perfectly known. The northern hemisphere had gradually become colder. Immense blocks of ice, descending from the sides of the mountains into the valleys and plains, had covered a considerable portion of Europe, Asia, and North America; and the temperature of our zône, till then torrid, had by degrees become frigid. The duration of this cold period, called the *glacial period*, was excessively long. After having attained their farthest limits, the glaciers retired considerably, then they advanced again, but without regaining their former position. This was the last phase of the tertiary epoch. The glacial period was nearly at an end. A gradual modification of temperature caused the melting of the ice, and the quaternary epoch commenced. The glaciers, those immense masses of snow, hardened by time and accumulated during thousands of ages, produced, when they melted, gigantic torrents, sweeping along in their powerful waves the ruins of mountains, flooding the plains, ploughing up the soil, hollowing the valleys and leaving in their track large deposits of sand, pebbles, and argile. From that epoch, called the *diluvian*, are dated our present rivers, but they give us in these days but a faint idea of what they were then.

The extraordinary power of the water floods was above all remarkable during the early part of the quaternary epoch; it gradually decreased from that time, but it was not until the glaciers had retired within their original bounds, until the temperature had become nearly equal to that of our own day, that the phenomenon of the great inundations ceased, and that the quaternary epoch drew to a close. Since that time, we still find sand and pebbles displaced, and sometimes even masses of more or less volume torn from the sides of the valleys by the torrents, but the rivers and streams no longer bear along with them more than particles of clay and slime, and these deposits have formed alluvial soil. The whole period which has elapsed since the close of the quaternary epoch bears the name of *present epoch*, and the soil which has been formed in this period is called *recent soil*. It is, certainly, recent, if we compare it with the quaternary soil, but not with reference to our ordinary chronology, for several hundreds of ages must necessarily have elapsed during its formation.

These considerations will aid us in comprehending the most essential facts which have served to establish the dates of human palæontology. These dates are determined in the first place by pure geology, in the second by palæontology, and in the third by prehistoric archæology.

The geological dates are chiefly inscribed in the valleys and in the plains, where the great floods of the quaternary epoch have left deposits in the shape of layers more or less regularly stratified. Except where some event has disturbed or excavated the soil, the layers are superposed in order of antiquity. The oldest are found beneath and are called low level; above them are ranged the middle level, which succeed them, and which are, in their turn, covered by the layers of the upper level, dating from the latter part of the quaternary epoch. We find a layer more or less thick of recent soil, formed of accretions, turf, vegetable matter, &c., covering almost all the quaternary soil.

It must suffice to explain in a general way how the study of the stratification of the layers, termed stratigraphy, enables us to determine the relative age of the recent or quaternary deposits. This primary classification is purely geological. Thanks to the data which it furnishes, we can calculate the period of existence of those animals whose bones are found in the different layers; these animals in their turn serve to characterise periods, and can thus establish the dates of certain soils, or of those partial deposits which do not form a part of a complete and regular stratification.

1. Among the animals living in our land at the beginning of the quaternary epoch, some, like the mammoth, no longer exist save in a fossil state; these are the extinct animals; others, like the reindeer, have disappeared from our climate, but still live in other regions; these are the

* Being the substance of the Address of M. Paul Broca to the French Association for the Advancement of Science, at the Session held at Bordeaux.

emigrant animals; others, like the horse, have survived to this day in our land, these are the existing animals.

The extinct animals abounded in the earlier quaternary age. Several were large and powerful mammalia, carrying terrible weapons of their own, and the human form looked weak and puny by their side. There were, among others, the great cave bear (*Ursus spelæus*), the great cave lion (*Felis spelæa*), the amphibious hippopotamus (*Hip. amphibius*), the rhinoceros with the expanded nostrils (*Rh. tichorhinus*), the ancient elephant (*Elephas antiquus*), finally and above all the giant, and we may say the king of this fauna, the mammoth (*Elephas primigenius*).

It would be superfluous to enumerate the other *extinct* species which lived at the same epoch. The reindeer and several animals, now *emigrants* like itself, were also to be found in this fauna, but they were still rare; and a good number of existing species had already made their appearance.

It is with good cause that the first period of the quaternary epoch, that which corresponds with the low level of the valleys has been called *the mammoth age*.

Every condition favourable to the prosperity of this species was then combined. But changes supervened which, in the long run, were to lead to its decay. The temperature had become less rigorous, and a great number of herbivora, till then stunted in their development by the inclemency of the atmosphere, had been able to improve and increase.

Already the mammoth saw arrayed against him the power of man, who, under this somewhat modified climate, could join in bands sufficiently formidable to declare war against him. Finally, and above all, this same climate, which suited his enemies and his rivals, had become hurtful to his own organisation, which required a colder temperature. The mammoth, therefore, so common in the earlier quaternary period, began to decline. We are inclined to think his existence was prolonged to the end of the palæontological age; but long ere that he had ceased to reign.

II. There was thus, in the middle of the quaternary epoch, an *intermediate age*, corresponding to the middle level of the valleys: an age in which several species contemporary with the mammoth were already extinct, in which others, represented only by solitary specimens, were on the point of disappearing, while those species were on the other hand flourishing, which were better adapted to the changing atmospheric conditions. Among these latter, the reindeer (*Cervus tarandus*) already occupied an important place, but it was in the succeeding period that it flourished.

III. This intermediate age gave way by degrees to the third and last stage of the quaternary epoch. When the layers of the upper level began to be formed, the species which we call extinct had almost entirely disappeared. A few rare mammoths still survived. Still more rare were the gigantic Irish deer (*Megaceros hibernicus*) and the great lion of the caverns. The rest of the fauna had but slightly changed, but the reindeer had multiplied to a wonderful extent. It formed at that time the chief nourishment of man. The third period of the quaternary epoch is therefore deservedly styled the Reindeer age.

The difference in the fauna of those days from that of our own time did not alone consist in the presence of the reindeer; many other hardy species, to whom a cold climate was necessary and a temperate one injurious, were still existing in our as yet frigid zone. When the state of the atmosphere more nearly approached that of the present day, there was a disappearance of the individuals which represented these species in our hills and plains; but the species themselves did not on that account perish. In the colder regions whither they had wandered they found a more congenial air, and they have thus been enabled to perpetuate themselves to the present time.

IV. The disappearance of the reindeer and of the other emigrant species marked the end of the quaternary epoch and of the palæontological age. Then began the modern epoch. Our climate was probably still a little colder than it is in our own days, but it was already temperate, and the slight changes which it has since undergone have not affected the conditions of life to such a degree as to endanger the existence of species. If the urus (*Bos primigenius*) and the aurochs (*Bison Europæus*) have disappeared from our land, we must attribute these results more to the destructive action of man than to that of climate,* and to man is also attributed the introduction of several new species, for the most part domestic animals. With these few exceptions, we may say that from the end of the quaternary epoch our fauna has not changed, and that the recent soil only contains existing species.

The dates which we seek to establish are therefore determined at the same time by stratification and palæontology. They also rest on data of another order, and these constitute a real science, namely prehistoric archæology.

The point which is certain and which has been irrevocably proved by Boucher de Perthes, is that the most ancient beds of the quaternary epoch contain vestiges of human industry. The knowledge of metals only dates, one may say, from yesterday; before possessing these powerful auxiliaries, man was not unarmed. In the manufacture of his weapons and tools he had employed several hard substances, the bones, the teeth of large animals, the horns of the Ruminantia, but above all, stone, and more particularly flint; hence the name *Stone age*, given in the history of man to all the period which preceded the use of metals.

This stone age still continues among some savage nations, and it only came to an end among the civilised people of antiquity at an epoch very little anterior to the historic age. Hence it embraces nearly the whole duration of human existence. Now the mode of fabricating weapons, their shape, their nature, must necessarily have varied during this immense period, according to the changes in the wants, the mode of life, and the social state of man who employed them; and if we now consider that hard stones will last an indefinite time in the ground, we shall understand that the tokens of this primitive industry constitute indelible medals and chronological documents of the highest importance.

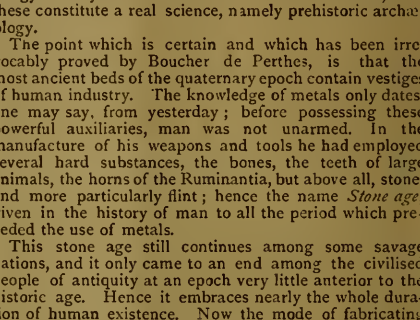

FIG. 2. FIG. 1.
The type of Saint Acheul; Hatchet carved on both sides. Fig. 1.—Front view. Fig. 2.—Edge view.

The dates established by prehistoric archæology agree pretty well, and sometimes coincide in a remarkable manner with those of palæontology and stratification,

* The urus is now extinct, but it is not more than three or four centuries since it existed in Germany and Great Britain. The aurochs is only to be found now in a forest of Lithuania, under the protection of a special law of the Russian Empire. A troop of them has been also seen in the Caucasus

Just as certain species of animals have perpetuated themselves since the earliest quaternary epoch, in like manner certain forms of hewn flint have been found almost without change through several archæological ages.

You have just seen that geologists have been able, more than once, to determine and designate an entire fauna from a single characteristic specimen; archæologists, in

FIG. 4. FIG. 5. FIG. 3.
The Moustier type: Lance Point carved on one side. Fig. 3.—The plain side, cut out with one stroke; the projection of the bulb of percussion is visible at the base. Fig. 4.—The carved side. Fig. 5.—Edge view.

like manner, have chosen in each case the most characteristic tool to distinguish the different periods of the Stone age. We cannot strictly determine these periods and their precise number, for working in flint may have had many modifications at the same epoch, but in different localities. However, in studying the question in its entirety, we may, following M. de Mortillet's example, reduce to three the number of archæological periods of the quaternary epoch.

I. The most remarkable type of the early quaternary age is the hatchet of St. Acheul (see Figs. 1 and 2). It is a flint of varying bulk, always rather large, longer than it is wide, thick in the centre, graduated towards the edges, presenting one extremity pointed, or rather arched, while the other is rather rounded; and the predominant characteristic is its being carved on both sides, and the sides are more or less convex and more or less symmetrical. This type abounds at St. Acheul, near Amiens, in the valley of the Somme, hence its name; but it has been found in most of the beds of the Mammoth Age. It is sometimes, but rarely, to be met with in less ancient beds.

II. A second epoch of the Stone Age is characterised by the point of Moustier (see Figs. 3, 4, and 5). This weapon, which was fixed to the end of a huge lance, presents an exterior contour not dissimilar to that of the hatchet of St. Acheul, unless, perhaps, in being slightly more pointed; but its distinguishing mark lies in its being carved on one side only; the other side is cut out with one stroke, and has not been retouched. It is not therefore biconvex, like the other, but planoconvex, and consequently half the thickness.

The Moustier type takes its name from the Moustier Cave, where it is very common. It was not common until the intermediate period.

III. The art of cutting flint was perfected in a third epoch, which corresponds with the Reindeer Age. The pointed or sharp-edged weapons became less massive; the contours and sides were more regular, more symmetrical, and a delicate touching up, in fine little strokes, graduated them towards the edges. This period of the Stone Age is less marked by the nature of the weapons than by the style of workmanship. It is, however, agreed to take as a type the lance point of Solutré, because a short time since the lances found at the station of Solutré, in Maçonnais, were the best-cut weapons that had been extracted from the quaternary beds (see Fig. 6); but, since then, Dr. Jules Parrot, and his brother M. Philippe Parrot, have found at Saint Martin d'Excideuil (Dordogne), in a cave of the Reindeer Age, several flints carved in a yet superior style.

IV. We have now arrived at the end of the Reindeer Age. Directly the present epoch opens upon us, we see apparent in the flint cutting a further improvement, which marks the commencement of a new archæological era. Up to this time the flint had only been fashioned by pressure or percussion. They had learnt, it is true, to round by friction some objects in stone in a very rough style, but the weapons and tools in flint were always hewn. In the new era now commencing, many weapons were still made of cut flints; but from that time forth they knew how to polish them, and the polished hatchet, too well known to need description, became man's principal auxiliary (see Fig. 7).

This hatchet characterises the epoch of polished stone, or the neolithic epoch, which terminates the age of stone, and which, consequently, lasts until the introduction of metals. The entire period preceding the appearance of the polished hatchet constitutes the epoch of hewn stone,

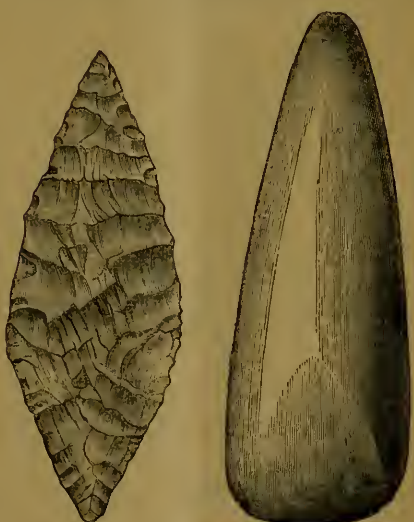

FIG. 6. FIG. 7.
FIG 6.—The type of Solutré: Lance Point of Solutré (Hamy. Human Palæontology). Fig. 7.—The Polished Hatchet.

which is also called the archæolithic epoch, or better still palæolithic.

The different phases of the epoch of hewn stone succeeded each other progressively, and by almost imperceptible transitions, like the corresponding geological periods; the epoch of polished stone, on the contrary, stands out clearly and almost abruptly from that which preceded it. Its commencement coincides exactly with the disappear-

ance of the reindeer, that is, with the end of the palæontological age, and with the commencement of the present epoch of geologists. It likewise coincides with a complete change in the social condition of man, with the domestication of the dog, with pastoral life, marked by the domestication of several herbivora, and soon after with agriculture. A long succession of ages then elapsed, until the appearance of bronze, which put an end to the Stone Age. The epoch of polished stone was therefore a very long one; compared to this the whole period of historic time sinks into insignificance: nevertheless, this period of polished stone, however long it may appear to us, was infinitely shorter than any of those of which the epoch of hewn stone is composed.

(*To be continued.*)

THE ITALIAN REPORT UPON THE ECLIPSE OF 1870*

THIS is a folio volume about an inch thick, in a yellow paper cover. It is a well-printed book, made of tolerably good foolscap, and as the title-page informs us, produced at the expense of the Italian Government, under the care of Prof. Sir G. Hunter, as we should call him, but in his native tongue, Il Cavaliere Professore G. Cacciatore †; and the first remark that occurs to one on looking through it is that whether the Government paid handsomely, or whether it gave with a grudging stinginess, its cash was at all events well laid out, alike without extravagance and without meanness, and that the result reflects honour upon Italy.

On dipping into its contents here and there in a cursory way, the next thing you notice is the eager interest which the several contributors seem to take in their work, and the earnest simplicity with which they recount their experiences and achievements.

Speaking generally, the volume is a picture-book; the plates, some of them distributed through the letterpress, but accumulated in a considerable mass at the end, form an important feature of it, and will be found very interesting and suggestive even to those who are not so fortunate as to read the text.

For the convenience of the latter class of persons, I propose now to give a slight sketch of the report, beginning at the preface, and describing the several papers in the order in which they occur; and if, whilst doing so, I should venture to make any comments, the reader must remember not to attach too much weight to them, because it is hardly possible for a foreigner to do justice to men whose words and ways must always bear from his point of view something of the interest proper to pictures by the old masters. I ought not to presume to review this book critically, because, in the first place, the chief performers concerned in it are in every way my superiors; and in the second place, I am obliged to confess at once that they are personally so vividly present in my memory, that it seems almost a rudeness to analyse their writing for public uses.

I find it impossible to eliminate the romantic charm of their manners, and my own recollections of the high courtesy they showed towards us when we were associated with them in Sicily.

A slight reflection of this latter will be perceived by the reader the first time he opens the book. Fronting the title-page he will find a lithographed drawing of the station at Augusta, purporting to show the several observatories, in which those of the Italian astronomers are shown in the background; whilst the rough shed of the English observers, and the tents in which they were encamped, form the most prominent features of the picture. In passing from this first page of the volume, I must testify to the singular faithfulness of the drawing.

After the title-page there occurs a short paragraph, consisting of Prof. Cacciatore's apology for the delay in the production of the Report. (By the way, I wonder what our unfortunate editor will say in this respect when, after we are all dead and turned to dust, he produces at his own untold expense the English report of the same eclipse as an astronomical curiosity! Is not that a rather pathetic and suggestive reflection?)

Next follows the index, and then an address to the Minister of Public Instruction, from which it appears that a royal decree of July 5 of the year previous to the eclipse appointed a Commission consisting of Professors Cacciatore, De Gasparis, Donati, Santini, and Schiaparelli "to draw up a programme of the observatories, and to appoint the persons, the instruments, and whatever might be considered necessary to the success of the enterprise"; and of this Commission, Prof. Santini of Padua. was appointed president, and Prof. Cacciatore, of Palermo, vice-president. This address is signed by Santini, and recounts further how the Commission assembled in Florence in September 1869, and added to its numbers Professors Padre Secchi and Pietro Blaserna, of which, and of all its other proceedings, the Minister had been kept informed. Santini goes on to say that his present duty is to express the thanks that Science owes to that official for the eagerness he showed in backing them up with a considerable augmentation of the fund originally appropriated, and getting placed at their disposal a Royal steamship, and so on.

He then says that, owing to his advanced age, the chief burden of the work fell to the lot of Cacciatore, and that, thanks to his careful diligence, and so on, things were got ready nearly as intended; the "nearly" being a consequence of the extraordinary political changes of the preceding year. Cacciatore however seems to have found it no joke, and the part confided to him, he says, was very arduous and rugged ("ben ardua e scabrosa").

Here follows Cacciatore's account (*relazione*) of all that he did, and it forms, perhaps, the most interesting chapter of the whole book. The rest of the observers pass before the reader in single file, each relating what he saw and did, in his own words; but Cacciatore gives us a peep behind the scenes, and tells us what was done in the way of preliminary arrangement, and how he tried to aid every man in the manner best calculated to develope his own particular abilities; and in these operations (if I may be allowed to pass a remark) he appears to have done his work in a masterly way; and he relates the story with a graceful facility that makes it most attractive reading. He describes his preliminary canter over the course of the totality in search of a suitable site for the observatories; tells how he first examined the neighbourhoods of Villa 'Smunda and Terranova, as affording beyond all doubt the most favourable conditions, and how he afterwards reluctantly abandoned the former on account of its unhealthiness, and fell back on Augusta for his chief station, the fortress of which he describes, and says he found it admirably adapted for the purpose. Most truly it was so; and if I were to give an account of it, I should find Cacciatore's allowance of adjectives very inadequate to convey my impression of its attractions, although December was by no means the month in which they could be fairly appreciated.

Leaving his colleague, Tacchini, there to make preparations, he returned to his observatory at Palermo, which formed the base of operations. After this he gives a summary of the instruments, the observers, and the *rôle* assigned to each, and tells how he marshalled them in two complete and independent divisions, one of them destined for Augusta and the other for Terranova. On November 25 the steamer *Plebiscito* cast anchor at Palermo, having

* Raporti sulle osservazioni dell'Eclisse totale di Sole del 22 Dicembre, 1870, eseguite in Sicilia dalla commissione Italiana.

† He always signs himself G. Cacciatore, but his first name is Gaetano.

picked up on her way from Genoa certain members of the expedition, with their instruments, and on the 27th they got under weigh again and proceeded to the east coast of the island, where they admired the scenery, and where their otherwise considerate and polite captain, Il Cavaliere Foscolo, strangely neglected the opportunity of running them ashore.*

Arriving thus at their citadel, nearly a month in advance, and finding that ample preparations had already been made, they were now in a position to devote themselves quietly to their own particular pursuits, and to carry on their experiments with reference to the important occasion. However, they were no sooner comfortably settled than their troubles began, somewhat after the fashion of Job's—"a great wind from the wilderness smote the four corners" of the fortress, and threatened to leave poor Cacciatore alone to tell the tale; and he seems to have had to put up with not a little "chaff" from his comforters as to his selection of a site; but he consoles himself with the thought that it would have been all the same if he had settled anywhere else.

Then follows a little paragraph about the English, which I may as wall translate:—"Meantime the most enlightened Prof. Adams, together with several of the numerous English Commission—others having remained in Catania—escaped from the misfortune of the *Psyche*, a magnificent steamer of the British Navy, stranded amongst the coasts of Acireale, arrived in Augusta for the observation of the phenomenon. Colonel Porter, of the Engineers, accompanied by soldiers of the same arm, having preceded them, visited our temporary establishment, passed graceful encomiums on the organisation, and planted tents and barracks (huts) at the foot of our fortress, and at the extremity of the open space which divided it from the town. With these distinguished gentlemen we maintained such friendly and cordial relations as are becoming between the citizens of cultivated and free nations."

The incidents of the three or four days preceding the eclipse, and the anxieties caused by the weather, are told with a graphic vividness that will cause those of us who were there to live over again through that period of painful suspense, a suspense only less felt by the English because of the demands made on their energies by the hurry and hard work of preparation. For we had to do in a five days' encampment in a foreign country what they very reasonably employed more than a month to do in their own. After describing the fitful changes of the wind, clouds, and barometer, which kept them oscillating between hope and dread up to the very beginning of the eclipse, he says: "And just then the sun appeared radiant and luminous, so as to provoke a cry of joy from as many as stood intent to observe him. So it went on until the moment of totality; but then some clouds began to traverse the obscured disc, and so rapid was their movement and their succession one after another, that they influenced the degree of visibility to each one of the observers in a different sense, and in such a fashion that there were some of them more fortunate and others less so." This admirably careful description corresponds perfectly with our own experience, and should be duly taken into account when the value of the observations comes to be considered. Cacciatore's own estimate of the work done, an estimate formed on the spot immediately after the eclipse, when he came to review his company, is expressed in reserved and general terms as follows:—"I was able to satisfy myself that alhough the sky was not largely propitious, it nevertheless conceded to us a certain interval, the fruits of which had been reaped to the utmost; and that if in general the observations of the eclipse of 1870 turned out unfortunate, the Augusta division would be able to supply facts which would not be without importance in the present state of science."

He then proceeds to summarise the results as follows:—

"Padre Secchi had assumed the photographic department, and the spectroscopic determination of the protuberances previous to the eclipse, with the view of being able to compare them with those which should be seen during the totality. The position and the shape of these were obtained on the morning of the same day, favoured by a fine serene sky. Ten photographs were made during the phases, and at the moment of totality photographs of the protuberances were obtained, in spite of the obstacle of a cloud. At the same time their forms were directly noted, and immediately afterwards were confronted with the spectroscopic figures. The spectrum of the most acute cusps of the sun was studied, and photographs of the later phases were taken until the end of the eclipse.

"Prof. Denza made spectroscopic observations of the corona, which discovered two bright lines, one near the E, the other probably of nitrogen (*dell' azoto*). Together with Signor De Lisa they observed and drew the protuberances.

"Prof. Donati in the time of totality was able to see the bright lines of one protuberance already studied before the eclipse. He saw the lines of hydrogen and one line in the yellow more refrangible than the sodium, but did not see any of the iron lines.

"Prof. Blaserna examined whether the corona contained polarised light. Employing a Savart polariscope applied to a refracting telescope of moderate magnifying power, he was able to examine three points situated at 45° from each other. The polarisation was most pronounced, and very nearly of the same intensity as the atmospheric polarisation seen recently on clear days at about 50° from the sun. At the distance of a degree and a half from the moon not a trace of polarisation was seen, the influence of the air, therefore, in the observed phenomenon remains eliminated. The plane of polarisation was found in all the points radial or tangential to the sun's limb. It remains then established that the corona is polarised, and hence contains reflected light sent out from the photosphere.

"The purely astronomical part assigned to me (the director) was, as far as the variable condition of the heavens admitted, fulfilled to the best of my ability. I was able, in fact, to note with some precision the instants of first contact, and the beginning of totality and the end of it (although the last through the clouds), besides some other observations which I shall refer to afterwards."

This summary concludes with a mention of the magnetic and meteorological observations, and the Professor goes on to remark concerning the station at Terranova, that the circumstances there were not dissimilar to those at Augusta—the same strong wind and clouds interfered as at the latter place.

Thus ends the general account of the operations described by the leader of the expedition—a most interesting introduction, and well worthy of the seven independent papers from Augusta which follow it, to which are added about the same number from Terranova, and some dozen more abridged accounts by outsiders, which form an appendix.

The leading place is accorded to that most accomplished of ecclesiastics, Father Secchi, who, in his ringing and trenchant style, gives a vivid picture of the whole experience, from the ordering of the instruments to the ultimate effect of the phenomenon. Next follows Donati, "in a speech curt tuscan, sober, expurgate, spare of an 'issimo,'" as Robert Browning says, in which the blunt but attractive manners of that genial soul are nearly as appreciable by the reader as if he were present in the flesh. After him Cacciatore details his own observations

* When it came to the knowledge of this gentleman (through the ever attentive Secchi) that our military escort, in consequence of "superior orders," had taken away our tents, and left us without shelter upon the open glacis at Augusta, he sent us a polite message, placing his ship at our service in the handsomest manner.

in his gracefully fluent yet finished style, and then come Blaserna's polariscopic experiments, clearly and energetically expressed, and, as far as I can judge, affording most conclusive results. It is not a little remarkable how much is contributed towards the value of the observations by the manner in which each observer relates them. The descriptions are given with such charming naïveté and absence of affectation, that the reader can appreciate almost the exact degree in which the writer's hand shook as he manipulated his instrument, not to speak of the degree in which his assertions can be relied upon for accuracy or freedom from bias.

JOHN BRETT

NOTES

M. JANSSEN has been elected a member of the Astronomical Section of the French Academy, the votes recorded for him being 42, against 13 for M. Loewy, and 1 for M. Wolff.

AT a recent meeting of the Natural Science Section of the Literary and Philosophical Society of Sheffield, a discussion took place on "The Attitude of the State to Science," in which Dr. Hime, Mr. Alfred H. Allen, Mr. H. C. Sorby, F.R.S., and Mr. J. Spear Parker successively took part, and the opinion of the meeting was embodied in the following resolution, which was passed unanimously:—"That this meeting deplores the supineness of the Government with respect to science, and believes that the national recognition of research, and the establishment of better means of rewarding discoverers, would be a direct benefit to the country."

IN order to remove any apprehension that might arise in the minds of some members of the Anthropological Institute (particularly of those residing in the country), from statements made that, in consequence of the recent change in the composition of the Council, a preference would be given to papers of an ethnographical class over those relating to other branches of anthropology, the director, with the full concurrence of the president, has thought it advisable to assure the members of the Institute that no such result need be feared. Papers on every branch of anthropology will always be cordially received, provided they comply with the requirements demanded in all communications to a Scientific Society intended for publication, amongst which, a very essential one is, that they should contain either "new facts or new applications of admitted facts." As a further assurance that all proper subjects will receive due and equal attention, it may be well to state in general terms what may be regarded as proper subjects to be brought before the Anthropological Institute. They may be included under the following heads:—(1) The Physical History of Man and of the Human Race; (2) Psychology; (3) Comparative Philology; (4) Priscan Archæology, *a* Prehistoric, *b* Protohistoric; (5) Descriptive Ethnography, comprising the Reports of Travellers and Explorers on the Physical Characters, Derivation and Relation, Manners, Customs, Religion, Language, &c., of various Races or Nations; (6) Comparative Ethnography; (7) The Relations between Civilised Man and Aboriginal Savage Peoples. In this programme it will be seen that any subject properly coming under the cognizance of the anthropologist may find a place. And in order to insure confidence that each and every subject will receive due attention, it is suggested that committees might, if thought desirable, be formed of such members of the institute as may take a special interest in any of the above branches of inquiry, whose function would be, each in its own sphere, to promote the collection of materials and the production of papers relating to the subject in which they may feel particular interest. In this way it is clear that all the subjects will be placed on an equality, and to be hoped that each in its turn will receive the same attention.

SOME weeks ago we expressed a hope that the vacant Swiney Lectureship would not be given to one who is already well off, but to some well-qualified young man, who would thus have leisure to perform work of high scientific value. Our hope, we are glad to see, has been essentially fulfilled in the appointment of Dr. Carpenter, who, unusually young in spirit, assuredly deserves the leisure which this appointment will ultimately help to bring him, leisure which, we have good reason to believe, will be devoted to the completion of work of very high scientific value indeed. Few men have devoted gratuitously more of their time to the public benefit, and we believe that he accepts the appointment mainly in order that he may have a good opportunity of working out in fuller detail the applications to geology of the inquiries in which he has been engaged during the last few years. Dr. Carpenter, we understand, has had by him for years, the material, fully worked out, of important papers which he has had no time to produce. Dr. Carpenter has once before held the Swiney Lectureship, and it has been offered to him again without any solicitation on his part.

ON Monday last, in the first of his Hunterian lectures for this year, Prof. Flower drew special attention to the peculiarities of a new animal discovered by Prof. Marsh, of Yale College, and named by him *Dinoceras mirabilis*. This remarkable ungualte, nearly the size of the elephant, was obtained from the Eocene beds of the Rocky Mountain region. It possessed osseous cores for three pairs of horns, which rise successively one above the other; a supra occipital crest is greatly developed, projecting obliquely backward beyond the condyles. The posterior pair of horns arise from this crest, the median from the maxillaries, and the anterior from the tips of the nasals. The canines are greatly developed, and the upper incisors are wanting. The skull is unusually long and narrow, and carries six small molar and premolar teeth. The extremities resembled very nearly those in the proboscidia, but were proportionately shorter. The femur possessed no third trochanter and no pit for the ligamentum teres. It therefore possesses characters allying it with the perissodactyles as well as the proscidia.

PROF. MARSH has also drawn attention to a new sub-class of fossil birds from the cretaceous shales of Kansas. The specimens, while possessing the scapular arch, wing, and leg-bones of the truly orthnithic type, present the very aberrant conditions of having biconcave vertebræ and well developed teeth in both jaws. These teeth are quite numerous and implanted in distinct sockets; the twenty in each ramus of the lower jaw are inclined backwards and resemble one another. The maxillary teeth are equally numerous and like those in the mandible. The sternum have a carina and elongated articulations for the coracoids. The lower of the posterior extremities resemble those of swimming birds. The last sacral vertebra is large, so it may have carried a tail. Professor Marsh proposes the name *Odontornithes* for the name of the new sub-class, and *Ichthyonithes* for the order to contain this remarkable species, which is about the size of a pigeon.

AT a meeting of the Senate of the University of London held last week, a resolution was passed by a majority of two, that it is desirable to make Greek an optional subject at the Matriculation Examination. The practical effect of the carrying ou

of this regulation will be, that while those who are intending to proceed to degrees in Arts will continue to take Greek at the matriculation, as a matter of course, it will not be required from those who are going on to degrees in Science or Medicine.

MR. A. W. BENNETT, M.A., B.Sc., F.L.S., has been elected Lecturer in Botany at St. Thomas's Hospital School of Medicine, in the place of the Rev. J. W. Hicks. A vacancy is thus caused in the Lectureship on Botany at the Westminster Hospita School.

THE following new candidates for the Professorship of Geology at Cambridge are announced:—Mr. William King, Professor of Mineralogy and Geology, Queen's College, Galway; and Mr. P. Brodie, M.A., F.G.S., of Emmanuel College, and Vicar of Rowington.

THE office of Chief Assistant in the Observatory, Cape of Good Hope, will be filled up by open competition on March 18 next, and the following days. Candidates must be between eighteen and twenty-five years of age, and the salary commences at 320*l.*, rising 10*l.* a year to 450*l.*

WE are really sorry to hear that the much-talked-of Arctic expedition of M. Pavy, who was recently fabled to have discovered an Arctic Continent, has vanished into worse than "thin air." It is perhaps unprecedented in the annals of science that the funds meant to be devoted to a noble and heroic purpose, should be literally wasted in riotous living. We hear, on too good authority, alas, that M. Pavy's explorations have been confined to certain not unknown phases of "life" in San Francisco.

COAL has been discovered on the railway from Mollendo to Arequipa in Peru. The seam is four yards thick. The coal has been reported as of good quality, and it is already being used on the railway.

DR. REISS, one of two German travellers in Ecuador, has succeeded not only in ascending Sotopax, but in entering the crater.

A GERMAN from Berlin has been for some time at Panama butterfly hunting. His first remittance was one hundred pounds' worth of butterflies.

ON December 28, 1872, a slight shock of earthquake was felt at Goalpara in Northern India, and again on January 3.

ON December 28, 1872, a strong earthquake was felt at 10 A.M., doing much damage at Chinameca, Salvador, Central America. It is attributed to the volcano of San Vicente, now in eruption.

ON January 1 there was a slight shock of earthquake at Guayaquil.

THE *Times of India* reports a sharp shock of earthquake which was felt on January 7, about 4 P.M., at the camp between Sultanpore and Fyzabad, in Oudh.

THE great shock of earthquake in Samos on January 31 happened at 1.10 A.M., and lasted 10 seconds. Several houses were thrown down, and many damaged.

THE French authorities at Tahiti report in their official journal that, in consequence of changes in the coast line and reefs, new rules for navigation have been issued. They announce, also, that the island placed in 21° 50' S., and 152° 20" W., does not exist, as the place has been sailed over by three vessels. Captain Truxton, of the U.S. ship *T. Jamestown*, has informed them that he has passed over the position of a reef assigned to 24° 45' S. and 150° 40' W., without seeing any token of danger.

M. DE FONVIELLE has been authorised by the French Academy to make a series of experiments on a new lightning conductor which he has devised.

THE Report of the Marlborough College Natural History Society for the half year ending Christmas, 1872, contains much that is of considerable interest and value, though we are sorry to see from the very honest preface, that the Society is not in so satisfactory a condition as it ought to and might be. While admitting that a fair amount of work has been done, the preface complains of the lack of interest in the work of the Society, and the comparatively small amount of energy displayed by many of the members. With regard to nearly all the sections, the tone of the preface is desponding, though hopeful that a change for the better may take place next year. The Society contains some excellent workers, who have shown no disposition to relax their efforts, and we earnestly hope that their example will be largely contagious, and that the next report will be written in a very different tone. It is a pity that a society so favourably situated in many respects as this is should not produce more abundant and more valuable results. The geological section, we are sorry to see, is nowhere, mainly for want of a permanent head. The society is also very much cramped for want of a suitable building for the museum. We hope this report will stimulate all the members to renewed activity; let them take to heart the very excellent advice given in the paper on "An Ideal School Natural History Society," by Mr. E. F. im Thurm, who deserves great praise for his efforts on behalf of the society. Appended are reports of the out-door work done in entomology and botany during the half year, and a long and very interesting paper by the Rev. J. A. Preston, describing what he saw on a recent visit to Brazil. The concluding article of the Report is Part I. of a carefully compiled descriptive Catalogue of the Archæological Collection of the Society, by Mr. F. E. Hulme, which is accompanied with a beautifully executed illustration of some of the articles in the collection.

AT the first meeting of the Sheffield Naturalists' Club held a few days ago, Mr. H. C. Sorby, the president, delivered a very excellent inaugural address, in which he gave his views as to the objects of the formation of such a society. Such a society as this, he said, had two characters. First of all, the subjective influence it had on the members who composed it. The study of natural history was most desirable in many ways. Man had a certain amount of energy; it must be expended in some way or other, and the examination into natural history furnished them with a study which was advantageous to both body and mind. By being joined together in a society they might greatly help one another. With regard to the objective value of such a society as this, he thought they ought not to limit their efforts to the mere making out of accurate lists of flora and fauna which occurred in the district. The efforts of naturalists also ought to be devoted to the discovery of general philosophical principles, as applied to both animals and plants. He thought they could learn a great deal more by the careful study of the commonest things than by looking for rarities. They could not hesitate in saying that a great deal remained to be done in the study of natural history in every district. The following, he thought, were some of the points which such a society should inquire into:—What is life, and how have the various species of animals and plants originated? Why do particular plants grow in particular localities? The determination of that question would have a most important bearing on geological theores. Another problem for study was what was the effect of dry or wet seasons on certain plants? If that question were settled, they might know the effect that must have been produced in bygone ages—by the alteration of climate—on certain plants and animals. Another most interesting subject for investigation was the influence of

plants on plants, animals on animals, and one on the other; the fertilisation of plants by insects, and the attractability of different colours for different insects. Other points recommended for study were the following:—The manner in which the habits of animals have been acquired; the manner in which varieties or species have been formed; the limit of the successive generation of insects through none but females; the diseases of plants due to parasitic fungi and insects.

THE first number of Petermann's *Mittheilungen* contains a brief account of the eruption of a new volcano in Chili, which occurred during part of last June and July. The volcano, known by the name of Lhagnell, is situated in the south of the country, in Arauco, between the volcanoes Villarico and Llaima, near the river Cautin. Immense quantities of sand seem to have been thrown out, some of which, according to Dr. Philippi, of Santiago, reached a distance of 300 or 400 miles north from the volcano. This sand is described as consisting of angular, transparent green particles of volcanic glass. Dr. Philippi also reports that for fourteen days, about midday, a strong south wind blew, as far north as Santiago, small quantities of sand, much coarser than the above, with rounded corners, opaque and grey. Great quantities of lava, according to the report of a spectator, have overflowed the district, causing considerable destruction to life, and stopping up the river Quepe, which is thus being converted into a considerable lake.

WE have received a small pamphlet, by Mr. B. H. Babbage, containing a description of a portion of the late Mr. C. Babbage's calculating machine or difference engine, put together in 1833, and now being exhibited in the educational division of the South Kensington Museum.

La Revue Scientifique for February 15, gives a summary of the much needed administrative reforms which have been introduced into the Collége de France.

WE have received the following papers recently read before the Eastbourne Natural History Society:—"On *Geoglossum difforme* or Earth-tongue," by Mr. C. J. Muller; "A Note on the Wall Pelletory," by Mr. F. C. S. Roper; "On the Planet Venus," by Mr. T. Ryle.

THE principal articles in the *Quarterly Journal of Science* are:—"On the Probability of Error in Experimental Research," by Mr. Crookes; "Condition of the Moon's surface," by Mr. R. A. Proctor, with photograph; "Colours and their Relations," by Mr. Mungo Ponton; and "Remarks on the Present State of the Devonian Question," by Mr. H. B. Woodward.

THE *Annual of the Royal School of Naval Architecture*, &c., contains some good technical papers. This publication will become vastly increased in importance, and we hope in value, by the establishment of the new school at Greenwich.

WE take the following from the *Engineer*:—The question as to whether a gasometer will explode when fired was settled in Manchester on Tuesday, February 11, when one of the gasometers at the Manchester Corporation Gasworks in Rochdale-road was destroyed by fire. The origin of the fire is not known, but about 2 o'clock a workman saw flames issuing from one end of the gasometers, and the flames could not be checked till the whole contents of the gasometer, about 600,000 cubic feet of gas, had been consumed. Many inhabitants of the neighbourhood hurried away with loads of their furniture, fearing an explosion, but nothing of the kind occurred.

ADVICES from Cyprus state that no rain had fallen on the island for months; but this is probably an exaggeration.

WE learn from the *Athenæum* that the Rev. Thomas Hincks, F.R.S., is now engaged in preparing a "History of the British Polyzoa."

PROFESSOR RAMSAY ON LAKES

PROF. RAMSAY, F.R.S., delivered a course of six lectures to working men, on Monday evenings, commencing Jan. 5, 1873, in the Lecture Theatre of the Geological Museum. The subject of the course was "Lakes, fresh and salt: their origin, and distribution in geographical space and in geological time," and the following is an abstract of them:—

I. FRESHWATER LAKES, THEIR ORIGIN AND GEOGRAPHICAL DISTRIBUTION

There are many classes of lakes in the world, formed in various ways, and though he had been unjustly charged with ascribing all lakes to one origin, he would be the last person to do so. He then went on to examine the various means which might be supposed to produce lake basins, and especially that class of lakes scattered over the whole northern hemisphere—in Wales, Cumberland, Scotland, Sweden and Norway, Russia, and N. America—the basins of which had evidently been formed by the erosion and grinding out of portions of the earth's crust. In many cases these lakes are in true rock basins, surrounded by lips of rock. How were these hollows produced by Nature? The dislocations of the earth's crust could not produce them; as a rule the sides of faults are close together or the fissure is filled up with other matter, and the depressions due to synclinal curves were never so simple or perfect as these lake basins, owing to violent disturbances, and to subsequent denudation. The theory of a special area of subsidence for each lake seems absurd, on considering the vast numbers of separate lakes, in N. America for example, lying in some case within a mile or two of each other. Again, a lake cannot make its own hollow; what little motion there is in the water can only affect the waste of the shores. Neither can a river scoop out a lake hollow, it can only produce a long narrow channel, and go on widening and deepening that, and the sediment which it carries down into the lake will in the long run fill up the lake basin. The action of the sea, too, on its shores cannot scoop out a lake hollow, it can merely wear back its cliffs and form a "plain of marine denudation" just below the level of its waters. And thus having exhausted all the other natural agencies which effect the denudation of the land, what agency remains to us to account for the formations of these lake basins, but the grinding power of ice? The lecturer then adverted to the phenomena of the formation and progress of glaciers, illustrating his remarks by diagrams of the great Rhone glacier. In the Alpine valleys there are numerous indications—in the mammellated surface of the rocks, the striation, moraines, and boulders—that at some period in the past all these glaciers had been very much more extensive than at present, and were found in many parts where now they are altogether wanting. In Greenland the whole country is covered by a universal ice sheet, which extends into the sea in some cases several miles, and where cliffs of ice rise out of the sea 200 to 300 ft. high, and, as recent soundings have shown, are sometimes 3,000 ft. deep. Large masses of these breaking off float away as icebergs, bearing with them stones and rubbish which they deposit, on melting, irregularly over the sea bottom. In the mountains of Wales and Scotland, in the Vosges, the Black Forest range, and in N. America are numerous signs of glacier action, all which prove that at one period, recent in a geological sense, glaciers were present in those districts; and boulders and boulder clay deposits show also that the Northern part of the Northern hemisphere was passing through a glacial epoch.

Boulder clay and moraines have sometimes dammed up a stream of water and formed a lake, but lakes of that kind are neither numerous nor of much importance. The theory that the true rock basins were scooped out by glaciers first occurred to the lecturer whilst observing in N. Wales, and he applied it first to the explanation of the tarns about Snowdon, but extended observation of the Italian and other great lakes, and subsequently of the American lakes, warranted him in applying it to them also. He had especially applied it to the Lake of Geneva, which lies directly in the course of the old Rhone glacier. The lake is 983 ft. in depth in its deepest part, nearly in the centre. Where the glacier entered the lake it could not have been less than 3,000 ft. thick, and as the rock underneath is comparatively of a soft character, where the ice was thickest the grinding power was greatest, and it scooped out its deepest hollow; but towards the south end the mass had grown less through melting, and the result was a shallowing of the basin It is in the valleys of Switzerland down which the glaciers must

formerly have extended that the lakes lie. The great depth of Lake Maggiore beneath the sea-level—2,300 ft.—is no argument against the theory, for a large mass of ice would block out the sea-waters. In Wales the lakes are never of large size, Lake Bala, the largest, being about 4½ miles long; Lake Windermere lies in a true rock basin, as do many others in that district; in Scotland, where the climate was more severe, the lakes are larger and more numerous; in Sweden and Norway, in Finland and N. Russia the lakes are almost innumerable, while in N. America they are scattered almost broadcast over the country N. of lat. 43°. Where the glacial action was most intense, there the lakes become more and more numerous, and he believed they were due not to special glaciers, like those on the south side of the Alps, but to that great ice sheet which, according to Agassiz, covered the whole country. In South America and New Zealand, too, are signs of a similar action, and there too, lakes of this class occur. The present glaciers of New Zealand are very small compared with what they evidently were at a previous period, and in the course of every one of them are lakes, which, according to reports he had received, also lie in true rock basins.

II. Salt Water Lakes, their Origin and Geographical Distribution

The lecturer said that he could not account for the origin of all salt-water lakes, but for some of them the evidence is clear, and it is plain to see why they are salt. The principal minerals forming the rocks of the earth's crust are silica, alumina, lime, potash, soda, magnesia, peroxide of iron, &c. Rain-water takes up from the atmosphere and the earth's surface a small proportion of carbonic acid, and thus acquires the power of dissolving certain of these minerals as it percolates through the rocks, notably lime, which it carries away in the form of a bi-carbonate. And thus the water of all springs is charged more or less with mineral ingredients, though these may be recognisable only by the skill of the chemist. Thus the water of the fountains in Trafalgar Square contain 69·75 grains of salts per gallon, including chloride of sodium 25·7; bi-carbonate of soda 14·5; sulphate of soda 18·4. The Thames water at Teddington contains 22·5 grains per gallon, and thus carries to the sea in the course of a year 377,000 tons of salts; the old well at Bath holds 144 grains of salts per gallon, thus bringing to the surface 608 tons of salts per year. The apparently small quantity of bi-carbonate of lime in a per-centage of the salts of sea-water, is still sufficient to furnish to marine creatures materials for their shells and skeletons, and thus indirectly to build up the great beds of limestone which are now in course of formation, or belong to former geological periods. The analyses of salts in sea-water and in the water of various lakes is given in the following table:

Per centage of	Mediterranean Sea.	Black Sea.	Sea of Azof.	Caspian Sea.	Dead Sea.
Chloride of Sodium.....	2·9460	1·4020	0·9658	0·3673	12·110
„ Magnesium	0·3223	0·1304	0·0887	0·0632	7·822
„ Calcium.....	—	—	—	—	2·455
„ Potash.......	0·0505	0·0189	0·0128	0·0076	1·217
Bromide of Magnesium	—	0·0005	0·0004	trace	
Sulphate of Lime	0·1357	0·0105	0·0288	0·0490	
„ Magnesium	0·2480	0·1470	0·0764	0·1239	
Bromide of Sodium	0·0558	—	—	—	0·452
Carbonate of Lime......	0·0113	0·0359	0·0022	0·0171	
„ Magnesia	—	0·0203	0·0129	0·0013	
Peroxide of Iron........	0·0004	—	—	—	
	3·7700	1·7661	1·1880	0·6294	24·056

Salt lakes though not so numerous as fresh-water lakes, occur in large numbers in certain regions. The Caspian Sea with an area as large as Spain, the Sea of Aral, and a vast number among the mountains and table-lands north of the Himalaya; the Dead Sea in Syria; L. Utah, and neighbouring lakes among the mountains on the western side of North America; and among the mountains of South America and in the interior of Australia are examples of large salt water lakes. It will be noticed that all these lakes lie in an area of inland drainage, that they have rivers running into them, but that they have no outlet. On inspecting the above table it will be seen that the Black Sea is fresher than the Mediterranean, by reason of the greater supply of fresh water furnished by the rivers, and Edward Forbes showed that this freshening has caused certain of the shells of Mediterranean species to assume "monstrous" shapes. The Caspian is still fresher, and its fauna and fossils in recent deposits in the neighbourhood prove it to have once had connection with the Black Sea, from which it has been separated by changes in physical geography; it was then salter than at present, but is now growing salter again every year, and the fauna now inhabiting its waters have likewise considerable affinities with North Sea types. Its surface level is 83·5 ft. below that of the Black Sea, while the surface of the Dead Sea is 1300 ft. below that of the Mediterranean. In all cases where rivers flow into depressions in the land, however these might have been formed (oscillating movements of the earth's crust might perhaps form such large ones as the Caspian basin), carrying with them certain salts in solution, if the lake have no outflowing river, the water must be carried away by evaporation, in which case the salts will be left behind, and the remaining waters become more and more saturated. It is stated that crystals of salt have been brought up from the Dead Sea, and on the shallow waters on its coasts evaporating in summer saline incrustations are left. The same water which flows *through* the Sea of Galilee, a fresh-water lake, renders the Dead Sea one of the most remarkable salt lakes in the world. And in this and all similar cases accumulation of salts will go on till the saturation point is reached, and then precipitation will commence. The region to the north of the Himalayas is comparatively rainless, owing to the mountains condensing the moisture carried by the south winds, and the rivers consequently do not carry into the lakes sufficient water to make them overflow their boundaries, hence they are salt. Lake Baikal, with an outlet to the sea, is quite fresh. For a similar reason the moisture from the south-west winds being condensed in great part by the Sierra Nevada, the lakes which lie in the great plains and table-lands to the east of that range have not a sufficient supply of water to cause them to overflow, and consequently they are salt, and are continually becoming salter. In 100 parts by weight of the water of the Great Salt Lake in that region, there are of chloride of sodium (common salt) 20·196; sulphate of soda 1·834; chloride of magnesia 0·252; chloride of calcium a trace, making a total of 22·282. And by means of the old water levels in the form of terraces round its margin, it can be proved that it has shrunk very considerably, and therefore its salts must be becoming very much concentrated. On the surrounding plains a saline efflorescence is found, which the lecturer believed might be explained by the rain which saturated the rocks during the rainy season rising again to the surface charged with salts dissolved from the rocks, during the intense heats of summer.

(*To be continued*).

SCIENTIFIC SERIALS

The *Zoologist* for January and February contains reviews of the works of Capt. Shelley and the late C. J. Andersson. Dr. Gray contributes a paper on the Cetacea of the British Seas, and Mr. Harting has a supplement to his paper on the British Heronries, a subject on which there are several letters also published. Messrs. Stevenson and J. H. Gurney, jun., send Ornithological notes from Norfolk, and Messrs. Gatcombe and Cordeux from Devon and Lincolnshire respectively.

The *Entomologist* for January and February, among other articles of interest, contains one by Mr. H. C. Lord, on "The Lepidoptera of Switzerland," as far as could be obtained in a twelve days stay. Out of the sixty-three species of butterflies met with, twenty-four are not British. Many of the English commonest forms are among the most frequently found there. *Colias Hyale* is commoner in some parts than *C. Edusa*, and *C. Helice* is not unfrequently found. Mr. F. Walker continues his papers on "Economy of Chalcidiæ."

SOCIETIES AND ACADEMIES

London

Royal Society, Jan. 9.—"On a new Method of viewing the Chromosphere," by J. N. Lockyer, F.R.S., and G. M. Seabroke.

The observations made by slitless spectroscopes during the eclipse of December 11, 1871, led one of us early this year to the conclusion that the most convenient and labour-saving contrivance for the daily observation of the chromosphere would be to photograph daily the image of a ring-slit, which should be coincident with an image of the chromosphere itself.

The same idea has since occurred to the other.

We therefore beg leave to send in a joint communication to the Royal Society on the subject, showing the manner in which this kind of observation can be carried out, remarking that, although the method still requires some instrumental details, which

will make its working more perfect, images of the chromosphere, almost in its entirety, have already been seen on several days during the present month and the latter part of last month.

The adaptation of this method to a telespectroscope will be seen at a glance from the accompanying drawing.

The image of the sun is brought to focus on a diaphragm having a circular disc of brass (in the centre) of the same size as the sun's image, so that the sun's light is obstructed and the chromospheric light is allowed to pass. The chromosphere is afterwards brought to a focus again at the position usually occupied by the slit of the spectroscope; and in the eye-piece is seen the chromosphere in circles corresponding to the "C" or other lines. The lens D is used to reduce the size of the sun's image, and keep it of the same size as the diaphragm at different times of the year; and the lenses F are used in order to reduce the size of the annulus of light to about $\frac{1}{8}$ inch, so that the pencils of light from either side of the annulus may not be too

FIG. 1.

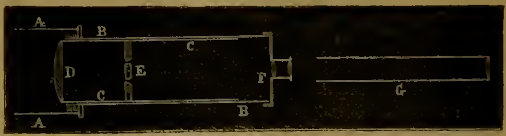

FIG. 2.

Fig. 1.—Diaphragm showing annulus, the breadth of which may be varied to suit the state of the air. The annulus is viewed and brought to focus by looking through apertures in the side of the tubes.—Fig. 2. A. Sliding eye-tube of telescope. B. Tube screwing into eye-tube. C. Tube sliding inside B, and carrying lens D and diaphragm E. F. Lenses bringing image of diaphragm to a focus at the place generally occupied by the slit of the spectroscope. G. Collimator of spectroscope.

divergent to pass through the prisms at the same time, and that the image of the whole annulus may be seen at once. There are mechanical difficulties in producing a perfect annulus of the required size, so one $\frac{1}{2}$ inch in diameter is used, and can be reduced virtually to any size at pleasure.

The proposed photographic arrangements are as follows:

A large Steinheil spectroscope is used, its usual slit being replaced by the ring one.

A solar beam is thrown along the axis of the collimator by a heliostat, and the sun's image is brought to focus on the ring-slit by a $3\frac{3}{4}$-inch object-glass, the solar image being made to fit the slit by a suitable lens.

By this method the image of the chromosphere received on the photographic plate can be obtained of a convenient size, as a telescope of any dimensions may be used for focussing the parallel beam which passes through the prisms on to the plate.

December 6, 1872, at 11.30.

December 7, 1872, at 11.30.

Outer circle 100 sec. from inner one. Chromosphere at normal height, except where prominences marked

The size of the image of the chromosphere obtained by the method adopted will be seen from the accompanying photograph, taken when the ring-slit was illuminated with the vapours of copper and cadmium.

As this photograph is not reproduced, it may be stated that the ring-images have an internal diameter of nearly $\frac{3}{4}$ of an inch.

The accompanying solar profiles are copies of drawing made, on the dates stated, by means of the new method, which were exhibited by the authors at the meeting.

[Since reading the above paper it has come to our knowledge that Zollner had conceived the same idea unknown to us, but had rejected it. Prof. Wenlock in America has tried a similar arrangement, but without success.—J.N.L., G.M.S., January 17, 1873.]

Feb. 13.—"On a new Relation between Heat and Electricity," by Frederick Guthrie.

It is found that the reaction between an electrified body and a neighbouring neutral one, whereby the eletricity in the neutral body is inductively decomposed and attraction produced, undergoes a modification when the neutral body is considerably heated.

Under many circumstances it is found that the electrified body is rapidly and completely discharged. The action of discharge is shown to depend mainly upon the following conditions:—(1) The temperature of the discharging body and its distance from the electrified one. (2) The nature (+ or −) of the latter's electricity.

With regard to (1), it is shown that the discharging power of a hot body diminishes with its distance and increases with its temperature. But, concerning the temperature, it is proved that the discharging power of a hot body does not depend upon the quantity of heat radiated from it to the electrified body, but chiefly upon its quality. Thus a white hot platinum wire connected with the earth may exercise an indefinitely greater discharging power, at the same distance, than a large mass of iron at 100° C., though the latter may impart more heat to the electrified body.

Neither the mere reception of heat, however intense, by the electrified body, unless the latter have such small capacity as to be itself intensely heated, discharges the electricity if the source of heat be distant: nor is discharge effected when the electrified body and a neighbouring cold one are surrounded by air through which intense heat is passing. But, for the discharge, it is necessary that heat of intensity pass to the electrified body from a neutral body, within inductive range.

White- and red-hot metallic neutral bodies exercise this discharging power even when isolated from the earth, but always with less facility than when earth-connected.

The hotter the discharging body, whether isolated or earth-connected, the more nearly alike do + or − electricities behave in being discharged; but at certain temperatures distinct differences are noticed. The — electricity, in all cases of difference, is discharged with greater facility than the +.

Attempts are made to measure the critical temperatures at which earth-connected hot iron (1) discharges + and — electricity with nearly the same facility, (2) begins, as it cools, to show a preferential power of discharging —, and (3) ceases to discharge —. The temperatures so obtained are measured by the number of heat-units, measured from 0° C. in 1 grm. of iron of the respective temperature, represented by the value of the expression $Fe\ \Sigma_0 u$.

It is shown that various flames, both earth-connected and isolated, have an exceedingly great power of discharging both kinds of electricity.

The effects in regard to discharge are shown to be similar when platinum wire, rendered hot by a galvanic current, is used, and also when the condensed electricity of a Leyden jar is experimented on.

As hot iron shows a preferential power of discharging — over + electricity, so it is found that white-hot but isolated iron refuses to be charged either with + or — electricity. As the iron cools it acquires first the power of receiving — and afterwards of receiving +. Further, while white-hot iron in contact with an electrified body prevents that body from retaining a charge of either kind of electricity, as it cools it permits a + charge to be received, and subsequently a — one.

A suggestion is made as to the existence of an electrical coercitive force, the presence of which, together with its diminution by heat would explain much of what has been described.

"On Curvature and Orthogonal Surfaces." By A. Cayley, F.R.S., Sadlerian Professor of Mathematics in the University of Cambridge.

Entomological Society.—February 3.—H. W. Bates, vice-president, in the chair.—Mr. F. Smith exhibited a box of Hymenoptera, collected near Calcutta, containing, amongst other insects, a new species of *Astata*, and four or five beautiful species of the genus *Nomia*.—Mr. McLachlan exhibited a quadrangular case formed by the larva of a trichopterous insect, taken by the Rev. A. E. Eaton in the river Dove in Derbyshire.—Mr. Champion exhibited specimens of a large species of *Pulex* found in a mouse's nest in Sheppy.—Mr. Meldola exhibited a living specimen of a myriapod of the genus *Spirobolus*, sent to him from San Francisco. Also eggs of a leaf insect from Java (*Phyllium pulchrifolium*).—Mr. Müller made remarks on pouch galls found on the leaves of cinnamon from Bombay.—Rev. Mr. Eaton read a paper on the *Hydroptilidæ*, a trichopterous family.—Mr. A. G. Butler communicated a monograph of the genus *Gasteracantha*, or crab-spiders.

Royal Microscopical Society, Feb. 5, Anniversary Meeting.—W. Kitchen Parker, F.R.S., in the chair. The report and treasurer's statement of account having been presented the president read a highly interesting address descriptive of his own further researches upon cranial development, which, during the year, had been chiefly confined to the formation of the skull of the pig. He briefly indicated the methods adopted, and some of the results obtained, and concluded by expressing the opinion that what he had already observed led him to conclude that if all existing forms had been really derived from one, the process must have been slow indeed. The report having been adopted, and some discussion having taken place as to the society's position, cordial votes of thanks to the retiring president, hon. secretary, and to the other officers of the society for their services during the past year were unanimously carried. The following is a list of the officers and council for the ensuing year:—President—Charles Brooke, M.A., F.R.S. Vice-Presidents—William B. Carpenter, M.D., F.R.S.; Sir John Lubbock, Bart., M.P., F.R.S.; William Kitchen Parker, F.R.S.; Francis H. Wenham, C.E. Treasurer—John Ware Stephenson, F.R.A.S. Secretaries—Henry J. Slack, F.G.S.; Charles Stewart, F.L.S. Council—James Bell, F.C.S.; John Berney; Robert Braithwaite, M.D., F.L.S.; William J. Gray, M.D.; Henry Lawson, M.D.; Benjamin T. Lowne, F.L.S.; Samuel J. McIntire; John Millar, F.L.S.; Henry Perigal, F.R.A.S.; Alfred Sanders; Charles Tyler, F.L.S.; Thomas C. White. Assistant Secretary—Walter W. Reeves.

MANCHESTER

Literary and Philosophical Society, Feb. 4.—Dr. J. P. Joule, F.R.S., &c., president, in the chair. E. W. Binney, F.R.S., paid a warm tribute to the memory of one of the most illustrious honorary members of the Society, the late Professor Sedgwick.—Prof. Williamson, F.R.S., stated that the second fossil plant described by Mr. Binney at the last meeting of the Society, Jan. 21, and of which a notice appeared in the Society's Proceedings, does not belong to some new genus, as Mr. Binney supposed, but is one that he has already described on two or three occasions as being the stem or branch of the well-known genus *Asterophyllites*. The author said that he had obtained the plant in almost every stage of its growth, from the youngest twig to the more matured stem, and that the genus would be the subject of his next, or fifth, of the series of memoirs now in course of publication by the Royal Society.—"On a large meteor seen on Feb. 3, 1873, at 10 P.M.," by Prof. Osborne Reynolds,* On Feb. 3, at 10h. 7m. (as afterwards appeared) by my watch (which was 7 minutes fast), I was walking from Manchester along the east side of the Oxford Road (which there runs 30° to the east of south), I had just reached the corner of Grafton-street, when I saw a most brilliant meteor. I first became aware of it from the brightness of the wall on my left, *i.e.*, on the north-east, which caused me to turn my head in that the wrong, direction; the first effect was that of a flash of lightning, but it continued and increased until it was equal to daylight. On lifting my head I saw directly in front of me, what had previously been hidden by the brim of my hat, a bright object, apparently fixed in the sky, as though it were coming directly towards me; immediately afterwards it turned to the west, and passed just under the moon (which it completely outshone). I was very much startled when I first caught sight of it, owing doubtless to the rapidity with which it was increasing in size, and the directness with which it seemed to be coming. The next instant I saw that it was only an extraordinary meteor. It passed the moon, falling at an angle of, I should say, 20°, and then ceased suddenly, having traversed a path of about 90°, from the south to the east. The colour of the light was that of a blue light, or rather burning magnesium. The sky was cloudy, but there was no appearance of redness about either the head or the train. I endeavoured to fix its course by the stars, but it was too cloudy, although I could see here and there a star. The conclusions I came to, there and then, were that its course must have been nearly parallel with the road, which by the map runs, at that point, 30° to the west of north; that when I first saw it it was about 40° above the horizon and due south; and that it passed about 20° to the north of the moon. (This would make its line of approach from Pegasus.) While I was thinking of its course I heard a report, not very loud, but which I connected with it. I judged it was about 30s after the display. I then looked at may watch; it was 10h. 7m. I then walked along, talking to a fellow-traveller who had not quite recovered his alarm. Presently we heard a loud report, like a short peal of thunder or the firing of a large cannon; I immediately looked at my watch, it was then 10h. 10m., so that this second report was from three to four minutes after the display. I have no doubt that this was the report of the meteor, for compared with the other it was like the firing of a cannon to a musket. The time of the second report would make the distance 30 or 40 miles, so that it would have passed over Chester and burst over Liverpool. In this case it must have been a tremendous affair, for the sky was cloudy, and I do not think I exaggerate when I say that at one instant it was as light as day; the train was very long, and the speed great. It ceased suddenly, as when a ball from a Roman candle falls into water; there were no fragments, as from an explosion.—"Note on a Meta-Vanadic Acid," by Dr. B. W. Gerland.—Dr. Roberts spoke on the subject of Biogenesis. (See his letter in this week's NATURE).—P.S. To Dr. Joule's description of a Mercurial Air-Pump.—The exhauster described in the last number (p. 296) has been further improved by dispensing with the glass tube *e*, and its stop-cock *f*. This is effected by attaching the base of the globe *b* to a strengthened india-rubber pipe, connected at the other end to a glass vessel of rather larger capacity than *b*. This vessel has only to be successively raised and lowered in order to exhaust the receiver. The mercury in the vessel may be either under atmospheric pressure or

* See NATURE, Feb. 6. p. 262. and Feb. 13, p. 290.

relieved therefrom. In the former case it must be alternately raised and depressed from 30 inches below *b* up to that level. In the latter it must be raised and depressed from the level of *b* to 30 inches above it. Castor oil is a useful medium to prevent the passage of air between mercury and the glass vessels. It is important to add a little sulphuric acid to the mercury, in order to remove the film of water which adheres to the inside of the globe *b*. On this account it would, perhaps, be desirable to substitute a plug of glass for the indiarubber one between *a* and *b*.

PARIS

Academy of Sciences, Feb. 10.—M. de Quatrefages, president, in the chair. M. Faye read an answer to Fathers Secchi and Tacchini's criticism on his recent paper on the solar spots. With regard to the assertion of the former that the gyratory motion of solar cyclones must be small, he replied by proving that it must be at least five times that of the most violent terrestrial cyclones; he then proceeded to answer the other objections in detail, and quoted a recent letter from Mr. Norman Lockyer, in opposition to the Rev. Father's theory of the spots being eruptions. MM. Becquerel and E. Becquerel then read a note on the temperature of soils, bare, and covered with vegetation, during rainy seasons. The bare soils are always at a lower temperature.—M. Daubrée read a note on two meteorites which fell, one at Montlivant in 1838, and the other at Beust in 1859, and also a communication on a new arrangement of the meteorite collection in the Museum d'Histoire Naturelle.—M. des Cloiseaux read a note on the determination of the form of amblygonite crystals; and M. Trécul the third part of his paper on the carpellary theory of the *Papaveraceæ* (*Chelidonium Macleya*), and on the same subject as regards the *Fossiflora Laudoni*. These papers were followed by one by M. de Caligny on certain works used in canal navigation. Notes on vine sickness and Phylloxera were received from MM. Marès, de Luca, Fancon, Nourrigat, Jeanheury, and Madame Vivien Jaworsta. A letter from M. Is. Pierre on the density of absolutely pure alcohol was read.—M. Janssen was then elected to the astronomical section in succession to the late M. Laugier. Out of fifty-six votes he obtained forty-two, M. Loewy thirteen, and M. Wolff one. M. A. Cornu read a paper on a new determination of the velocity of light. His determinations agree well with those of Foucault.—A note on the electric resistance of metals was then read.—M. V. de Luynes sent a note on the annealing of glass.—MM. Rabuteau and Ducoudray one on the toxic properties of calcic salts. The authors state that metals are more poisonous as their atomic weights increase, and compare calcium with strontium and barium, both of which are poisonous to a considerable extent.—M. F. Papillon sent a second note on experimental researches on the modification of the composition of bone.—M. Champouillon one on the properties of silicate of soda, &c.—M. S. de Luca one on a stalagmitic body from the solfaterra of Pozzuoli.—Messrs. Lockyer and Seabroke sent a description of their method of observing the solar prominences with an annular slit; this was followed by a paper on the "Heat of Transformation," by M. J. Moutier; and one on the maximum resistance of galvanometers, by M. Th. du Moncel.—MM. Laussedat and Magnin sent a note on the use of the pocket aneroid and on a new hypsometric formula of great simplicity.—M. E. Bourgoin sent a paper on the action of bromine on di-bromosuccinic acid. The author has thus obtained a hydride of tetra-brominated ethylene.—M. F. Hamel sent a note on a new red colouring matter from aniline. The body in question is produced by acting on aniline with chloride of sulphur.—M. J. Carlet sent a description of a new osmometer.—M. Locari sent a paper on the presence of human bones in the osseous brecchia of Corsica; and M. E. T. Hamy one on the age of the fossil men of Guadeloup.—M. W. de Fonvielle sent a description of a new lightning conductor. The session then adjourned.

WESTERN YUNAN

A Report on the Expedition to Western Yunan, viâ Bhamô. By John Anderson, M.D. (Calcutta: Office of the Superintendent of Government Printing, 1871.)

THIS interesting volume consists of the first section of a report on the expedition from Burmah over the Chinese frontier into Yunan, sent out under the auspices of the British Government, in the year 1868. It was under the charge of Major Sladen and Captain Williams, with the author, Dr. Anderson, as naturalist to the Expedition. They were accompanied by Messrs. Bowers, Stewart, and Burn, as representatives of the commercial community at Rangoon; the main object in view being to ascertain how far it was possible for the great highway to China by the valley of the Tapeng, could be made open to British commerce. The desirability of this access to the western frontiers of China has long been felt, and many attempts have been made during the last two centuries to establish an emporium either at Bhamô or in its neighbourhood, and one of the results of the recent expedition has been the sanction on the part of the Burmese Government of the residence of a British representative at Bhamô for the protection of our commercial interests.

The first part of the volume before us is chiefly historical, and deals with the relations of the ancient Shan kingdom of Pong, with the neighbouring States of Burmah and China, and the wars which resulted in Pong becoming a Burmese province. The wars between China and Burmah are also described, but during the last hundred years or more the intercourse between the two nations has been one of peace.

The European intercourse with Bhamô is next traced from the days of Marco Polo downwards; for from some of the details given by that traveller as to the customs of the inhabitants of the province of Kardandan, there can be but little doubt that his route must in part at least have almost coincided with that of the expedition.

The description of the physical features and geology of the Bhamô district and of Western Yunan forms an interesting and important chapter. At Bhamô itself the Irawady, though 600 miles from the sea, is one and a half miles in breadth during the heavy rains, and about a mile during the dry season. Its great valley is, however, in places broken up by low isolated ranges which confine its waters to comparatively narrow but deep channels. These hill ranges are usually of metamorphic and crystalline rocks on which Eocene and Miocene strata, consisting of limestone, sandstone, clay, coal, and ferruginous conglomerates, have been deposited together with interbedded traps. The Tapeng, along the valley of which the course of the expedition lay, has a course of about 150 miles from its rise in the Kananzan hills to its confluence with the Irawady above Bhamô. For a considerable portion of this distance there is a continued succession of waterfalls and rapids, though it is navigable for about twenty miles when it reaches the Burmese plain. The Kakhyen hills through which it passes attain a height of 5,000 or 6,000 ft., and appear to be mainly composed of metamorphic and crystalline rocks. Their surface, even to the highest peaks, is strewn with water-worn boulders, to which Dr. Anderson assigns a marine origin, believing that since their deposit this tract of country has been raised from beneath the sea, and that the immense valley of the Irawady was subsequently excavated. The Kananzan range appears to attain an elevation of about 9,000 ft., and to consist of rocks of the same character.

The Nantin valley leading to Momien seems to belong to another geological age, as in that district there has been a comparatively recent outflow of trappean rocks, while the country to the west is exclusively granitic and metamorphic. There, as well as in the Sanda Valley, are hot springs which issue at almost the boiling-point, and at the head of the Nantin valley is the large extinct volcano of Hawshuenshan. An extremely interesting feature in this valley and lower down the stream in the Mawphoo gorge, consists in the well-marked river terraces. Two of these seem to extend the whole length of the valley of Nantin—about sixteen miles—and there are indications of a third at a still higher level.

Of the mineral products, the coal seems to hold out the promise of good fuel and in fair quantity. It crops out on the surface in several places on the right bank of the Irawady, but as yet has been but little worked. Its geological age has yet to be determined.

Galena, rich in silver, is found in the valley of the Tapeng, and gold also occurs, sometimes in grains as large as small peas. The most interesting products of this part of Burmah are, however, amber and jade. The amber mines are at an elevation of about 1,050 ft., in a low range of hills to the S.W. of the Meinkhoom plain, in the Hukong valley. It is procured in a primitive manner by digging holes about 3 ft. in diameter, and sometimes as much as 40 ft. in depth. "Fifteen to twenty feet of the superficial soil is clayey and red, but the remainder consists of a greyish black carbonaceous earth. Foliated limestone, serpentine, and coal, are among the other strata. The amber is found in both of the former, and its presence is indicated by small pieces of lignite which are easily detected." It is made into Buddhist rosaries, finger-rings, pipe mouth-pieces, &c. The dark sherry-coloured amber is most highly valued.

Jade is found in more or less rounded boulders embedded in a reddish yellow clay. Pits are sunk in search of it on no defined plan, and at certain seasons of the year there are as many as 1,000 men engaged in digging for jade in the Mogoung districts. Blocks are occasionally found so large that they require three men to turn them. Everything in connection with the trade is taxed—diggers, purchasers, jade, and even the ponies used for its transport—and the revenue from the mines was, in 1836, about 4,000*l*. The jade used to be largely worked at Momien, and the manufacture is still carried on there to some extent. It is cut by means of thin copper discs about eighteen inches in diameter, used in conjunction with fine siliceous grit, composed of quartz and little particles resembling ruby dust. The boring of ear-rings and bracelets is effected by a revolving cylinder tipped at the free end with the same siliceous mixture. The most valuable jade is of an intense bright green colour, but the red and pale pink varieties are also prized. A pair

of bracelets of the finest jade costs about 10*l.* at Momien.

At some remote period the jade appears to have been applied to useful rather than to ornamental purposes, for celts formed of this material are found all over the district, lying on the surface soil, and doubtless turned up by the plough. They have also been formed of various other rocks, such as quartz, Lydian-stone, green-stone, clay-slate, &c. Lithographic plates are given of twenty-three of these instruments of various size, form, and material; but about 150 were procured by different members of the expedition. A good series of them has been presented to the Christy collection by Major Sladen.

A bronze celt, socketed, but without any side loop, and of peculiar form, with an oblique segmental cutting edge, was also procured. These are so highly valued that as much as 5*l.* apiece was asked for them. The composition, curiously enough, is identical with that usual in European antiquities of the same class, being 9 of copper to 1 of tin. The stone celts being more abundant than those in bronze, were less valued, being sold in the bazaars and elsewhere at from 4*d.* to 1*s.* 6*d.* each. Both they and the bronze celts are regarded as thunderbolts, which, after they fall and penetrate the earth, take nine years to work their way up to the surface. Not only is this belief in the celestial origin of these implements common to Asia and Europe, but the healing powers attributed to them in most European countries, are also accorded them in Yunan. They are worn as charms and carefully kept in small bags; and water, in which they have been placed, is administered as a medicine, especially in the case of tedious labour. It is rather a compliment to the students of prehistoric archæology that the only objects thought worthy of being figured by Dr. Anderson should be these celts.

The ethnological details given by the author as to the Shans, and what may be regarded as the transitional varieties between them and the Burmese on the one side, and the Chinese on the other, are highly interesting. A more barbarous people with whom the expedition was brought in contact, are Kakhyens or Chingpaws, who, though hemmed in on either side by Buddhist nations, still retain an ancient worship of good and evil spirits whom they call "nâts," and to whom they are constantly making propitiatory offerings of pigs, fowls, and rice.

Their method of producing fire is very remarkable, and is effected by "the sudden and forcible descent of a piston in a closed cylinder. There is a small cup-shaped cavity at the end of the piston rod, into which a little tinder is inserted. The piston is then introduced into the cylinder, which it tightly fits, and by a blow is made to descend with great rapidity and force, and is as rapidly withdrawn, when the little pellet of tinder is found to have become ignited." The instruments are not more than four inches long, and are in general use. It would be highly interesting to trace the origin and date of this invention.

At Bhamô one of the articles exposed for sale in the shops was flint, which would therefore appear to be the fire-producing material of the Burmese-Shans. Iron is abundant, and the Chinese-Shans, who resort annually to Bhamô for the purpose of manufacturing the dâhs or swords, are expert blacksmiths, their bellows consisting of a segment of bamboo with a piston, and a valve at each end.

Among some of the Shan tribes neck-rings or *torques*, curiously like those found in Western Europe, are still in use; but the majority of the ornaments appear to be Chinese in character. It would, however, extend this notice beyond all reasonable limits were an attempt made to give even a short abstract of the chapter on the Shans, Kakhyens and other races to the east of Bhamô. The curious practice of horse-worship in connection with the Buddhism of the Sanda Valley may, however, be noticed, as well as the Shan method of concealment of gold and precious stones, by burying them beneath the skin of their chest and necks by making slits, through which the coins or stones are forced, and which subsequently heal up. When the valuable object is wanted a second cut is made upon the spot, and it is extracted. In some instances, as many as fifteen stones or coins were found to be hidden beneath the skin of men just arrived with a caravan at Mandalay. It is needless to follow the author in his report on the Mahomedans in Yunan, the presence of whom, however, proved of great service to the expedition, as many of their guard were of that religion, and thus found friends. Nor need the trade routes of Upper Burmah be here discussed. The geographer will find much information in the chapter on the Irawady and its sources, and in the accompanying map. This chapter concludes the Report, and the remainder of the volume contains the diary of the author, written during the expedition. His report on the Natural History collections formed during his travels, has yet to appear, and will no doubt contain curious details. Even now we may call attention to the remarkable instance of the taming of fishes in a large river like the Irawady, by the phoongyees or Buddhist priests. At the boatman's cry of *tit, tit, tit*, numbers of fish came to be fed with rice and plantains, putting their heads above water, allowing themselves to be stroked, and even permitting Dr. Anderson to put his fist into their mouths so as to feel their teeth. He was unable to procure a specimen, as there were strict orders from the king that they should not be killed.

With this anecdote we must conclude our notice of this interesting Report, and must express a hope that a certain number of copies of it may be consigned to some London publisher so that it may become accessible to the general public, which as yet it apparently is not.

JOHN EVANS

THE HYGIENE OF AIR AND WATER

The Hygiene of Air and Water. Being a Popular Account of the Effects of the Impurities of Air and Water, their Detection, and the Modes of remedying them. By William Proctor, M.D., F.C.S., Surgeon to the York Dispensary, and formerly Lecturer on Chemistry and Forensic Medicine in the York School of Medicine. (Hardwicke.)

THIS is a useful little book, but it wants some revising: it is too sweeping a statement to say that the oxygen of the air is constant in amount and the carbonic acid variable; it is true that the variations in the amount of oxygen are very small in proportion to that amount. It would have been well to state even in a popular treatise

that other substances besides ozone affect Schönbein's papers, which are not "browned" by the way.

We are glad to see that the organic impurities introduced into the air by the respiration of animals receive due attention, and that the gradual deterioration of health caused by breathing impure air is well insisted on.

The pages on the ventilation of sewers, &c., want rewriting, and the three conclusions all require alteration; they are as follows:—

1. "That no sewers, or drains, or pipes, should run into drains in dwelling houses." This sentence as it stands is too ambiguous to be of any value.

2. "If this be impracticable, all sink pipes or waste pipes should be broken off at least one foot above the trapped grating into which they discharge." The first clause here is unnecessary and even misleading; it would be well left out.

3. "On no account should a cesspool be placed within the walls of a dwelling, but as far as possible from the house." Surely it would have been well here to advise the abolition of these nuisances where not absolutely impracticable, or at any rate their construction of suitable impervious materials.

This is certainly the weakest part of the book, and shows how little such matters are generally understood even yet.

On the other hand the remarks on the relations of filth and disease are excellent: "the negligence of the upper and lower classes of society alike, in these matters, entails terrible calamities on both. The fevers and contagious disorders arising from the neglect of the poor, either on their own or on our part, find their way into the dwellings of all classes, and equally establish disease. The poorer class cannot with impunity live in a state of unnecessary filth and dirt; neither, on the other hand, may the rich without danger neglect the sanitary and physical conditions of the poor around them."

The currents of air produced in rooms by differences in the temperature of various parts should, if classed with winds (the aspirating effect of which latter is not mentioned), be at any rate in a separate subsection; and the law of diffusion of gases does not hold for vapours, and it is certainly not in virtue of it that "the dispersion of vaporous matter" in the air is effected. Otherwise the pages on ventilation are well worth study, and the same may be said of the part devoted to disinfectants, which contains much sound practical information.

The second part of the book, on "the impurities of water and their removal," is decidedly good; some of the best known cases illustrating the connection between polluted water and specimens of cholera and enteric fever are given, and the dangers to be apprehended from the habitual imbibition of impure water (apart from specific diseases) are insisted on; the presence of more than a small amount of chlorides is rightly pointed out as a suspicious circumstance, and the simpler tests for the detection of the various impurities are concisely described; then follows a short account of the methods to be employed for the purification of presumably impure water by means of boiling, filtration, &c., and several of the best household filters are mentioned. Clark's process is, however, only casually alluded to, and not by name.

We are glad to find that the importance of a *continuous water supply* especially to the poorer classes is pointed out.

The book before us will, with a small amount of correction, do valuable service if widely circulated, as we have little doubt that it will be. If we have drawn attention to a few defects in it, we have done so because we believe that it is of the utmost importance that popular manuals should contain exact information, and enter as little as possible into disputed points. W. H. C.

OUR BOOK SHELF

The Coal-fields of Great Britain, &c. By Edward Hull, M.A., F.R.S., &c. Third edition. (London: Stanford.)

THIS new edition of Prof. Hull's well-known work is in most respects a great improvement upon the previous ones. Not only are the coal-fields of Britain itself treated of in more detail, but those of the colonies and foreign countries also come in for fuller notice. The introduction of numerous excellent maps illustrative of the English coal fields imparts an additional value to the volume, by enabling the reader to grasp at a glance the leading features in the geological structure of the districts embraced. Prof Hull has, moreover, largely availed himself of the report prepared by the recent Coal Commission, the chief results of which have been embodied in his work. That report, as everyone knows, has calmed the fears of those who saw looming in the near future the exhaustion of our coal supplies and the consequent decline of our industries. It is comfortable to reflect upon the fact that we have still 146,480 millions of tons available within a depth of 4,000 feet, and something like 48,465 millions of tons at a greater depth. From the first of these estimates, Prof. Hull would deduct one-twentieth for coal-seams under two feet in thickness, thus leaving the available quantity of 139,156 millions of tons lying within a depth of 4,000 feet from the surface. Beyond this depth he believes it will not be practicable to penetrate, owing to the effect of increasing temperature and pressure. This, however, is quite an open question. No good reason can be shown why ventilation should not be made effective at a still greater depth than 4,000 feet. If the deeper-lying coal should ever be needed no doubt the engineers of the future will be equal to the occasion and able to render it available. Then, as regards the effect of pressure, we know from actual experience that the "density of coal-seams is not perceptibly greater at 500 or 600 yards than at half that depth." One might almost have inferred as much beforehand, for many of our coal-fields which are now being worked at easy depths must at one time have been covered with thousands of feet of strata, long since removed by denudation; yet the seams in such fields are not denser than those of fields which do not appear to have been covered by such great rock masses. Again, we have heard mining engineers assert that the increased pressure in the deeper pits actually aids in the excavation of the coal, which comes away in larger lumps than would be the case with a similar coal in shallower workings. But whether or not it will ever be necessary to sink deeper than 4,000 feet, there can be no doubt that there is yet abundance of fuel above that limit to keep our furnaces going for many long years to come, and if Britain be destined ere long to retire from her place in the vanguard of nations her loss of prestige will probably be due to other causes than the exhaustion of her mineral resources.

The author expresses himself strongly on the subject of "waste" in working the coal, but not a whit more strongly than is necessary. Everyone who has any acquaintance with British collieries knows how lamentably great this waste is, amounting in some cases to so much as 40 per cent. No doubt, in many of our best conducted collieries waste is reduced to a minimum, but there is still woful

need for improvement in this matter. It is, of course, impossible for Government to interfere in squabbles about disputed boundaries, &c., and hence jealousy and stubbornness will continue to put considerable areas of coal beyond the chance of being "won." But surely something might be done towards increasing the number of our mining schools; and, as Prof. Hull suggests, the Legislature might establish some educational test without which no one should be allowed to have the supervision of colliery workings. With well-educated managers the waste of coal arising from ignorant methods of working would be checked, and we should hear less frequently of those frightful accidents which ever and anon throw whole mining communities into mourning. J. G.

The Natural History of Plants. By H. Baillon; translated by M. M. Hartog. Vol II. (London: L. Reeve and Co., 1872.)

PURSUING the somewhat erratic arrangement to which we alluded in our notice of the first volume of this work (see NATURE, vol. iv. p. 199), Prof. Baillon proceeds to an account of the small order of Connaraceæ, the three sections of the large order Leguminosæ, viz., Mimoseæ, Cæsalpinieæ, and Papilionaceæ, and then goes off at a tangent to four orders of Incompletæ, viz., Proteaceæ, Lauraceæ, Elæagnaceæ, and Myristacaceæ. The same plan is pursued as in the first volume, of giving first of all a general sketch of the characters of the order, and then dividing it into a number of "series," each containing one or more genera. An immense mass of information is thus collected, though wanting in convenient arrangement. The references to original authorities are, however, commendably copious. The illustrations, as before, are excellent, the translation apparently well and carefully done.

Memorandum des Travaux de Botanique et de Physiologie végétale qui ont été publiés par l'Académie Royale de Belgique pendant le premier siècle de son existence, 1772—1871. Rapport Séculaire per E. Morren. (Bruxelles: Hayez, 1872.)

THOUGH Belgium has not produced any botanical star of the first magnitude, yet a large amount of excellent work has been done in the little kingdom, especially during the period of its independent existence, since 1830, as shown by the labours of Decaisne in the flora of Japan, and of Galeotti in that of Mexico, of Jean Kickx in cryptogamic botany, of Charles Morren in teratology and general morphology, and of Quetelet in the periodic phenomena of vegetation. M. E. Morren's short abstract of the service done by his countrymen in each department of botany, with a list of the dates of publication of the various memoirs, is a useful contribution to the history of the science.

Results of Five Years' Meteorological Observations for Hobart Town.

WE are here presented with carefully constructed tables and valuable remarks on the climate and vital statistics of Tasmania. It includes the results of observations for the five years ending in 1870, with which are incorporated the statistics for the previous twenty-five years, so that it presents us with a complete set of statistics of meteorology for thirty years. That the observations have been carefully and correctly made is proved by the fact that the results of thirty years' observations agree very closely with those of the twenty-five years, the difference in many cases amounting to only a second or third place of decimals. The observations for the five years ending 1870, have been made gratuitously at the Toronto Observatory, by Mr. Francis Abbott, the tables having been constructed by Mr. T. Roblin, Curator of the Museum, and revised by Dr. E. Swarbeck Hall, who appends an elaborate and carefully drawn up health report for Tasmania. The introduction, among other matters, contains a descriptive list of the various instruments used; the set seems to be complete, and all the apparatus trustworthy. The following are the mean resultants from the thirty years' observations for Hobart Town from 1841 to 1870 inclusive:—Barometer (at temperature 32°), 29·580. Thermometer, mean temperature, 54·72; mean diurnal range, 17·91; mean solar intensity, 93·39; mean terrestrial radiation, 43·01. Humidity of air—Dew point—mean position, 45·49; humidity of air, 75; elastic force of vapour, ·316; condensation, rain in inches, 1 89; number of days on which rain fell, 11 66; Ozone, mean daily amount, 7 24; prevailing direction of wind, N W., S.E.; prevailing force of wind, 58 37 lbs. per square foot.

Jahrbuch der k k. Geologischen Reichsanstalt, xxii. band, No. 2. (Wien.)

FRANZ RITTER V. HAUER gives, in this number of the Year-book, an outline sketch of the sedimentary formations met with in Austria. He arranges his materials somewhat after the manner of Studer's "Index der Petrographie," the names of the various deposits following in alphabetical order. The geological horizons are briefly indicated, and copious references to authorities are given. The descriptions are necessarily brief, but they are clear and comprehensive, and the paper will be invaluable to those who may desire to widen their acquaintance with Austrian geology. Among the mineralogical contributions, we notice the description of a new mineral from Mexico—*Guadalcazerite,* the composition of which is given as $6\ H_g\ S + Z_n\ S$. From the laboratory of Prof. Bauer come several useful rock-analyses, chiefly ironstones. Professor Tschermak gives a description of sundry meteorites, and some account of basalts, metaphyres, and other eruptive rocks from the Caucasus. There is also an interesting paper by Professor Inostranzeff on the Vesuvian lavas of 1871 and 1872.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Prof. Balfour Stewart on the Spectroscope

I BEG to say a few words in reply to some statements in the letter of Prof. Balfour Stewart in NATURE, February 20.

1st. I wish to state that I had no knowledge of Mr. Proctor's letter in the *English Mechanic* until I saw it by accident in a copy of that journal which had been sent to me for another matter. I have never made the claim to which Prof. Stewart refers.

2nd. The note in Schellen's "Spectrum Analysis," of which Prof. Stewart asks an explanation, consists of three statements of fact.

α "Though to Mr. Lockyer is due the first publication of the idea of the possibility of applying the spectroscope to observe the red flames in sunshine, as a matter of history it should not be passed over that about the same time the same idea occurred independently to Mr. Stone, of Greenwich, and to Mr. Huggins." I wish to remark that I made no claim on Mr. Stone's part or on my own. On the contrary I said expressly "*as a matter of history*" these facts should not be passed over. I conceive that this statement of facts ought to have a place in a book which professes to give the history of the subject.

β "These observers were, however, unsuccessful in numerous attempts which they made to see the spectra of the prominences, for the reason probably that the spectroscopes they employed were not of sufficient dispersive power to make the bright lines of the solar flames easily visible." Prof. Stewart remarks that he "cannot yet understand" why I failed. The reasons can now be a matter of conjecture only. All workers in science know how much more difficult it is to discover the unknown than to recognise the known. It may be that I passed over too carelessly the deep red (C) and the blue (F) where the brightest lines occur. The observation of the bright lines in the star in Corona B (May 1866), in which the same sifting principle of the prism came into operation, should have suggested to me to look for the lines of

hyrdogen. Later (June 1867) Mr. Johnstone Stoney showed, in an important paper on the "Constitution of the Sun and Stars," that hydrogen was to be expected. I acknowledge that I ought to have found the lines.

γ "When the position of the lines was known, Huggins saw them instantly with the same spectroscope which he had previously used in vain." Of course in this remark I refer only to my own experience; I do not wish to be thought to imply that such assistance was either needed or received in the case of any other observer. Prof. Stewart asks why I did not see the lines sooner after receiving the news from India. This question awakens painful memories. At the time the Indian reports reached me I was watching by the bed of the dying, and a few days afterwards I suffered so severe a bereavement that I was unable to resume work in the observatory until the beginning of December, when I saw the lines. WILLIAM HUGGINS

The Beginnings of Life

IT seems advisable for me not to pass without comment the communication made by Dr. Wm. Roberts, of Manchester, in last week's NATURE.

Dr. Roberts calls attention to what he considers two possible sources of error in my experiments. The first is the "possibility of the introduction of atmospheric germs at the moment of sealing the vessels," owing, as he says, to the fact "that the sealing can only take place just as ebullition is about to cease," and to the consequent risk of some "reflux of air into the flask." After Dr. Roberts has made a series of experiments similar to those which have been recently cited in these columns (see NATURE, Feb. 6, p. 275 with *Erratum* in Feb. 13, p. 296), he may perhaps be a little less apprehensive as to this source of contamination. It is, however, not the fact that flasks cannot be sealed during ebullition, and this I shall be very happy to demonstrate to Dr. Roberts. Moreover, if he will refer to Dr. Sanderson's letter, Dr. Roberts will find that in speaking of the sealing of the flasks in the blow-pipe flame, he says care was taken "to continue the ebullition to the last." And in several series of experiments M. Pasteur also made use of flasks which had been sealed during ebullition—believing that in so doing he was experimenting with vessels from which all living germs had been excluded. Speaking of the preparation of such flasks, Pasteur says (*Ann. de Chim. et de Physique*, 1862, p. 74): "je ferme l'extremité effilée pendant l'ebullition. Le vide se trouve fait dans les ballons." No one has hitherto questioned M. Pasteur's skill as an experimenter.

The second alleged source of error is, according to Dr. Roberts, much more important. My mode of experimentation, he says, "does not insure that the entire contents of the flask are effectively exposed to the boiling heat." Although Dr. Roberts confirms my statement that many fluids treated in the manner I have described do soon swarm with living things, he seems to think their appearance may be due to the fact that several of the mixtures "froth excessively in boiling, and spurt about particles which adhere to the glass, and probably some of these escape the full effect of the heat." I feel quite sure that in my experiments no portion of the inner surface of the glass has escaped the scathing action of the boiling fluid. The vessel has generally been more than three-fourths full before the process of heating has been commenced, so that when ebullition occurs the fluid has always swept over the previously uncovered inner surface and, as Dr. Sanderson testifies, "during the boiling some of the liquid was frequently ejected from the almost capillary orifice of the retort." The inner surface of the vessel was, in fact, always thoroughly and repeatedly washed with the boiling fluid, nearly half of which has been spurted away in order that I might effect this object

Dr. Roberts says:—"Dr. Sanderson is, however, careful not to endorse the conclusions which Dr. Bastian has drawn from these experiments." But this is scarcely a fair statement, since Dr. Sanderson had near the beginning of his letter announced his intention of taking no part in the controversy. Dr. Sanderson's opinions, however, on the elements of the question have already been set forth (see Thirteenth Report of Medical Officer of Privy Council, p. 59). Whilst not believing in the danger of atmospheric contamination by Bacteria germs, he does believe, in common with other biologists, that immersion in boiling liquids is a ready means of destroying them. If Dr. Sanderson had not thought that the conditions of the experiments were such as to be exclusive of the intervention of living germs, why should he have previously doubted "my statements of fact" in respect to them? Does Dr. Roberts consider Dr. Sanderson so much of a tyro in these matters as to suppose that he would doubt the well-known fact that living germs will always rapidly multiply in suitable fluids? If not, then the only other source of doubt that could have arisen, must have been as to the possibility of the appearance of swarms of living things in hermetically sealed vessels in which all pre-existing organisms had been killed. And if Dr. Roberts wishes ample proof that such has been the view also entertained by others I need only refer him to the last few pages of a curious article (purporting to be a review of my work "The Beginnings of Life"), which appeared in a recent number of a journal (*Quart. Journ. of Micros. Science*) of which Mr. Ray Lankester is one of the editors. It is perhaps fortunate for the reviewer's reputation and for his fame as a scientific experimenter that his name does not appear, or that his unsuccessful experiments, destined to upset my views, were not published before the advent of Dr. Sanderson's letter.

In some respects the actual results of the experiments performed by Dr. Roberts differ from those of other experimenters. Thus he has found that filtered infusions of any animal or vegetable substances can be "invariably preserved unchanged when boiled for five or ten minutes in a flask plugged with cotton wool." The results obtained by M. Victor Meunier and by myself have been different, and we have both shown that they are apt to vary according to the strength and nature of the infusions employed. Dr. Roberts says he has also found that many "highly putrescent mixtures" remained perfectly barren "after the flask containing them had been immersed in a water-bath kept at a boiling heat for twenty or thirty minutes," although several of the same mixtures "could not be kept unchanged by simple boiling over the flame," and the sealing of the flask during ebullition. If, after what I have already said concerning the latter mode of experimentation, anything is to be deduced from these facts, it would perhaps be that the partial vacuum within the flask is more favourable to the initiation of putrefactive changes in some boiled fluids than their contact with filtered air. This is what I have always thought, and evidence pointing that way may be found in *Appendix* C of my "Beginnings of Life." Certainly one cannot assent to the conclusion which Dr. Roberts would draw from such experiments, based upon the supposition that the boiling of the sealed flasks in water is a protective measure. Dr. Roberts' results are here again somewhat different from others which have long become matters of history. Need I say that this was essentially the method of experimentation introduced more than a century ago by Needham, and that his results were confirmed by his adversary, Spallanzani, who says: "L'ebullition d'une demi-heure ne fut pas un obstacle à la naissance des animalcules du dernier ordre qui peuplèrent toujours, plus ou moins, tous les vases exposés à son action pendant tout ce temps-là." Does Dr. Roberts forget that Dr. Wyman boiled his flasks for two hours and yet obtained positive results? that he boiled others in a Papin's digester under a pressure of two and five atmospheres respectively, and still obtained living organisms from his flasks. Must I also remind him of the numerous experiments by Prof. Cantoni, of Pavia, in which the hermetically sealed flasks were heated in a Papin's digester to temperatures ranging from 100°—117° C.; and to several of the experiments that I have myself recorded in which undoubtedly—living organisms were obtained from flasks that had been heated in fluids raised to temperatures varying from 130°—153° C. (*e.g.* such experiments as are recorded in "The Beginnings of Life," vol. i. pp. 441, 443, 447, and 463).

When will those who do me the honour of referring to my experiments look all round and cease to argue from one half of the facts? H. CHARLTON BASTIAN

University College, Feb. 24

Himalayan Ferns

DURING the years 1861–66 I took every available opportunity to collect ferns in the Sevalik and Himalaya ranges. There being at that period no published work on the ferns of British India, and one subsequently published in Madras not having come under my notice, my specimens, several hundred in number, and all well dried, remain unclassified.

Would this collection be of any scientific value, and if so, to what society could I present it? I opine it would be worse than useless to offer it to the herbarium of the British Museum, as there it might remain untouched for the next fifty years; whilst at Kew I presume Hooker's superior collection would render my poor mite useless.

If not worthy of presentation to any herbarium, would any competent botanist classify it for the sake of the duplicates?

F. G. S. P.

General Travelling Notes

DURING the years 1857–66 I was in India, and in that period travelled much, both in the Plains and the interior of the Himalaya.

Since my return to England I have constantly regretted that I took few notes, and those few notes, from lack of knowledge, of little or no value, on flora, fauna, geology, and altitudes. In a few months I shall return to the same part of India (North West Provinces and Punjâb), and purpose remaining in that country for some years. There are many men in the army who, like myself, have a general taste for scientific observations, but our efforts end in gratifying our own minds only, our observations lacking sufficient accuracy and classification, whilst much is overlooked from sheer ignorance as to the how and where to look.

To the end that I (and others of like mind) may, perchance, furnish some useful jottings during my next term of foreign service, can any contributor to NATURE inform me where the following are to be met with :—

1. A plain code of what to look for and observe, after the manner of, but shorter than, "The Scientific Orders of the *Challenger*," published in NATURE for Jan. 9 and 30.

2. What is the best text-book on each head (*e.g.* on barometrical and thermometrical observations, Indian geology, botany, &c.). It is very essential each such text-book should be comprised in one handy volume; if possible as clear and concise as Tyndall's "Lectures on Electricity."

3. What instruments should be taken. I suggest—An ordinary thermometer, tested at Kew; a max. and a min thermometer; an aneroid (of what size?); a prismatic compass; an Abney's clinometer-level for ascertaining the slope and consequent height of mountains and depths of valleys roughly; also a small *portable* rain-gauge, if such is made; a simple microscope, and a magnifying glass. Are these sufficient? and if so, where should they be procured, and at what price? the *cost* being a vital point.

4. Can these, or similar instruments, be obtained in a single case sufficiently small to be carried, like a small theodolite box, in one hand?

F. G. S. P.

Mirage

THE following references to the literature of this subject are in answer to the note by Prof. J D. Everett in NATURE for January 2 last :—

A. RAMSAY

Brilliant Meteor of Feb. 3

TO supplement Prof. Osborne Reynolds' interesting paper on the meteor of February 3, which he saw in Manchester, and which he thinks must have passed over Chester and Liverpool (NATURE, February 20, p. 315), I enclose you a cutting from a local Cheshire paper showing that this meteor *was* seen about the same time in Northwich, which is some twenty-five or thirty miles S.W. from Manchester, and almost in a direct line drawn from Manchester to Chester.

By consulting the various local papers published in Northwich, Chester, Birkenhead, Liverpool, &c., it could easily be discovered at what place it was last seen, and where the loudest explosion was heard, and so the approximate path of this splendid meteor and its height might be traced out. These papers will mostly all be found in the Exchange and the Athenæum Reading Rooms, Manchester, where I believe they are regularly filed.

Merton College, Oxford J. P. EARWAKER

"A METEOR SHOWER AT NORTHWICH.—At Northwich on Monday night, February 3, about ten o'clock, a very brilliant meteor was observed in the sky passing from east to west. The meteor displayed an intense white light in its course, and emitted sparks which appeared of various hues. It was visible about six or eight seconds, and from one to two minutes after the passage of the meteor a loud rumbling report like distant thunder was heard. The night was very clear, and starlight at the time."

A VERY bright meteor was imperfectly seen here by me at 9h 58m on Monday evening, February 3. At the time of its appearance the sky was much clouded though not entirely overcast and became suddenly illuminated by what I at first considered to be flashes of lightning. The clouds in the north sky particularly were illuminated, and as I thought it possible that the phenomenon might be due to the appearance of a large fire-ball behind the clouds, I noted the exact situation in which the greatest quantity of light (which was about equal to the moon when five days past conjunction) existed. This was, as accurately as could possibly be determined, at a place about 10° eastward of the north point, or north by east, and in the vicinity of the horizon. When traversing this part of its path it is possible that the meteor was at its brightest, and on the point of disappearance. It was impossible to note any further details as to the exact course of the luminous appearances seen inasmuch as but few stars were perceptible, and the north sky was much obscured by cumulus clouds. This meteor was also seen at Manchester at 9h 57m; it appeared near the zenith of that station.

Bristol WILLIAM F. DENNING

Inherited Feeling

AS every instance of inherited antipathy in the offspring of Turk adds to the weight of proof, I beg to state that a mastiff in my possession, a grandson of Turk, and a brother of Mr. Brooke's dog, showed the same unaccountable antipathy to butchers, manifesting violent rage when any one of that honourable fraternity showed himself in the yard where he was kept. He was otherwise of a remarkably mild and gentle disposition.

Bowdon, near Manchester, ARTHUR RANSOM
Feb. 21

WOULD it not test the correctness of Mr. Wallace's ingenious theory as to animals finding their way back over an unseen country by their sense of smell, to shut up a cat in a basket along with a piece of stale fish, the scent of which would certainly overpower any external scent by which it might be able to trace the way back? It seems to me that many instances are on record of this curious power of certain animals, especially of cats, which are quite inexplicable on Mr. Wallace's hypothesis.

ALFRED W. BENNETT

External Perception in Dogs

THE view to which Mr. Wallace gives expression in your last number had occurred also to me, and I should like, with your leave, to offer a remark or two in support of it.

That a dog shut up in a basket may through smell acquire a series of impressions so definitely marked as to be able therewith to find its way back to the place it was taken from, becomes less improbable if we think what is the part that must be played by smell in its ordinary objective experience. Our external world (whether as actually perceived or imaginatively represented) may be called a world of sights and touches, blended with and modifying each other in the most intimate way. These mutually involved sights and touches, in our consciousness, are run out into the form of a *continuum* in space (how or why it is not to

the present purpose to inquire), while all other sensations, as of hearing, smell, and taste, come before us only discontinuously and intermittently, not being had from all things nor always from the same things. But in a dog's experience touch cannot possibly co-operate with sight as it regularly does in ours. The organ of effective touch in man—touch that gets associated with vision—is in the last resort the hand, combining mobility and sensitiveness in the highest degree; and the dog has no hand. Its mobile limbs are not sensitive at the extremities, and, though it has sensitive lips, these, having no such active mobility as the human hand has, are extremely limited in the scope of their apprehension. Its touch being thus defective, what is there then in the dog to play second to sight, which as leader needs support, were it only because there is not always light to see with? Smell, I cannot but think, seeing that, while the organ is incontestably acute, it has the great advantage over the tactile surface of the lips, of receiving impressions from things already at a distance. If we only suppose—what the facts make very likely—that the dog's smell is acute enough to have some sensation from all bodies without exception, nothing more is wanting to enable a psychologist to understand that the dog's world may be in the main a world of sights and smells continuous in space. In that case a dog conveyed in a basket might by smell alone find its way back pretty much as a man blindfolded finds his way by touch alone.

To argue properly so difficult a question is impossible in a short letter, and I must be content now, for reasons like those indicated rather than stated above, with giving my adhesion to Mr. Wallace's view—so far at least as dogs are concerned, and to the extent that in smell we have a source of explanation for the phenomena which has never been sufficiently considered. That the explanation covers all the facts related even about dogs is more than I would assert; and whether it is equally serviceable for other animals like cats and horses, concerning which not less wonderful stories are told, is not so clear. Cats, however, seem to have very acute smell. What is the truth about the smell of horses?

Fiords and Glacial Action

IN NATURE, vol. vii. pp. 94, 95, I find the following:—

"*Poggendorf's Annalen*—A. Helland adduces a large amount of evidence to show that the fiords in Norway have been formed by glacial action."

It appears an obvious remark, and yet I have not met with it, that fiords are chiefly found in those coasts where from the geographical conditions there must have been the most glacial action. The most favourable conditions for glacial action are evidently those of a mountainous coast in a high and therefore cold latitude, fronting the rain and snow-laden west winds of the higher latitudes as they blow in from the ocean. These conditions are fulfilled in the highest degree by the coasts of Norway and Western Scotland: the western coast of North America from Vancouver's Island northwards; and the western coast of South America from Chiloe southwards; and these coasts are accordingly more cut up into fiords than any others in the world.

The western coast of America along the enormously long line from Vancouver's Island to Chiloe is one of the most unbroken in the world. It is significant that the change in the coast at Chiloe from an unbroken one to one very much broken into fiords is accompanied by a great and comparatively abrupt change in the height of perpetual snow on the Andes. The following are the heights of perpetual snow at three different latitudes, according to Mrs. Somerville's "Physical Geography." The first two are north of Chiloe, the third south of it.

About 33° S. (near Valparaiso) . . .	12,780 feet
„ 37° 40′ S.	7,960 „
„ 53° (Strait of Magellan)	3,390 „

Although the height of the snow-line depends chiefly on latitude, it is sensibly influenced by the aspect of the mountains respecting the rain and snow-bearing winds. The best instance of this is probably that of the Himalayas, where, according to Mrs. Somerville (page 314), the height of the snow-line is 16,620 feet on the north side, and only 12,980 on the south. According to another authority (Capt Strachey), quoted by Mrs. Somerville (p. 54), the heights are 19,000 to 20,000 feet on the north side, and 15,500 on the southern. The difference of the two estimates is about the same. The reason of the difference is evidently that the south side receives the moisture-laden winds from the Indian Ocean.

Old Forge, Dunmurry JOSEPH JOHN MURPHY

NOTE ON A POLYDACTYLOUS CAT FROM COOKHAM-DEAN

BY the kindness of Dr. Plumbe, of Maidenhead, I have been able to procure one of these cats; and from the many curious points he possesses, I think a note on his peculiarities will interest some of the readers of NATURE.

Readers of Mr. Darwin's "Origin of Species" are familiar enough with the illustration he gives of correlation of arrest of development in the deafness of blue-eyed cats. Some years ago I showed that our great naturalist had fallen into error on this point, and that the correlation is not between the blue eyes and the deafness, but between the latter and the sex of the cat.

I have made a great many inquiries on this point, and have completely confirmed my former observation, that all perfectly white tom-cats are deaf, and that they have blue eyes occasionally, because that item of beauty is common among white cats. I have seen many white Tabithas with blue eyes, but none of them were deaf. My little "Pudge" from Cookham is perfectly deaf, and has one blue eye and a yellow one. For the first few days after I had him, I thought he could hear a little, but am now quite satisfied that his deafness is complete, though he is alive to sounds conveyed through solid media. A further point of interest is that he is not mute as most deafs are, but there is a kittenish shrillness in his voice and a loudness in his purring, which are not commensurate with his age. I think, therefore, that it is possible that early in life he may have heard a little, for I know of two instances where perfect mutism accompanied the deafness in cats, and I do not know of any contrary condition. The one yellow eye favours my view that "Pudge" may have heard in infancy his mother's voice. His sense of touch is extremely acute compared to that of another cat I have, but his sight does not seem so sharp as that of cats generally is. He has twenty-six digits, and these are arranged—seven on each fore limb, and six on each hind limb. The supernumerary digits on the fore limbs are thumbs, and are placed one on either side of the true pollex, being joined to it, but having no metacarpal bones. In the hind limb the supernumerary digit is probably of the same nature, or a supernumerary index, being placed on the outer side of the hallux, and attached to the tarsus by a completely-developed metatarsal bone.

LAWSON TAIT

ON ACTION AT A DISTANCE*

I HAVE no new discovery to bring before you this evening. I must ask you to go over very old ground, and to turn your attention to a question which has been raised again and again ever since men began to think.

The question is that of the transmission of force. We see that bodies at a distance from each other exert a mutual influence on each other's motion. Does this mutual action depend on the existence of some third thing, some medium of communication, occupying the space between the bodies, or do the bodies act on each other immediately without the intervention of anything else?

The mode in which Faraday was accustomed to look at phenomena of this kind differs from that adopted by many other modern inquirers, and my special aim will be to enable you to place yourselves at Faraday's point of view, and to point out the scientific value of that con-

* Lecture delivered at the Royal Institution, Feb. 21, 1873, by Prof. Clerk Maxwell.

ception of *lines of force* which, in his hands, became the key to the science of electricity.

When we observe one body acting on another at a distance, before we assume that this action is direct and immediate, we generally inquire whether there is any material connection between the two bodies, and if we find strings, or rods, or mechanism of any kind, capable of accounting for the observed action between the bodies, we prefer to explain the action by means of these intermediate connections, rather than to admit the notion of direct action at a distance.

Thus when we ring a bell by means of a wire, the successive parts of the wire are first tightened and then moved, till at last the bell is rung at a distance by a process in which all the intermediate particles of the wire have taken part one after the other. We may ring a bell at a distance in other ways, as by forcing air into a long tube at the other end of which is a cylinder with a piston which is made to fly out and strike the bell. We may also use a wire, but instead of pulling it, we may connect it at one end with a voltaic battery, and at the other with an electro-magnet, and thus ring the bell by electricity.

Here are three different ways of ringing a bell. They all agree, however, in the circumstance that between the ringer and the bell there is an unbroken line of communication, and that at every point of this line some physical process goes on by which the action is transmitted from one end to the other. The process of transmission is not instantaneous, but gradual, so that there is an interval of time after the impulse has been given to one extremity of the line of communication, during which the impulse is on its way, but has not reached the other end.

It is clear, therefore, that in many cases the action between bodies at a distance may be accounted for by a series of actions between each successive pair of a series of bodies which occupy the intermediate space, and it is asked, by the advocates of mediate action, whether, in those cases in which we cannot perceive the intermediate agency, it is not more philosophical to admit the existence of a medium which we cannot at present perceive, than to assert that a body can act at a place where it is not.

To a person ignorant of the properties of air, the transmission of force by means of that invisible medium would appear as unaccountable as any other example of action at a distance, and yet in this case we can explain the whole process, and determine the rate at which the action is passed on from one portion to another of the medium.

Why then should we not admit that the familiar mode of communicating motion by pushing and pulling with our hands is the type and exemplification of all action between bodies, even in cases in which we can observe nothing between the bodies which appears to take part in the action?

Here for instance is a kind of attraction with which Prof. Guthrie has made us familiar. A disc is set in vibration, and is then brought near a light suspended body, which immediately begins to move towards the disc as if drawn towards it by an invisible cord. What is this cord? Sir W. Thomson has pointed out that in a moving fluid the pressure is least where the velocity is greatest. The velocity of the vibratory motion of the air is greatest nearest the disc. Hence the pressure of the air on the suspended body is less on the side nearest the disc than on the opposite side, the body yields to the greater pressure, and moves toward the disc.

The disc, therefore, does not act where it is not. It sets the air next it in motion by pushing it, this motion is communicated to more and more distant portions of the air in turn, and thus the pressures on opposite sides of the suspended body are rendered unequal, and it moves towards the disc in consequence of the excess of pressure. The force is therefore a force of the old school—a case of *vis à tergo*, a shove from behind.

The advocates of the doctrine of action at a distance, however, have not been put to silence by such arguments. What right, say they, have we to assert that a body cannot act where it is not? Do we not see an instance of action at a distance in the case of a magnet, which acts on another magnet not only at a distance, but with the most complete indifference to the nature of the matter which occupies the intervening space? If the action depends on something occupying the space between the two magnets, it cannot surely be a matter of indifference whether this space is filled with air or not, or whether wood, glass, or copper, be placed between the magnets.

Besides this, Newton's law of gravitation, which every astronomical observation only tends to establish more firmly, asserts not only that the heavenly bodies act on one another across immense intervals of space, but that two portions of matter, the one buried a thousand miles deep in the interior of the earth, and the other a hundred thousand miles deep in the body of the sun, act on one another with exactly the same force as if the strata beneath which each is buried had been non-existent. If any medium takes part in transmitting this action, it must surely make some difference whether the space between the bodies contains nothing but this medium, or whether it is occupied by the dense matter of the earth or of the sun.

But the advocates of direct action at a distance are not content with instances of this kind, in which the phenomena, even at first sight, appear to favour their doctrine. They push their operations into the enemy's camp, and maintain that even when the action is apparently the pressure of contiguous portions of matter, the contiguity is only apparent—that a space *always* intervenes between the bodies which act on each other. They assert, in short, that so far from action at a distance being impossible, it is the only kind of action which ever occurs, and that the favourite old *vis à tergo* of the schools has no existence in nature, and exists only in the imagination of schoolmen.

The best way to prove that when one body pushes another it does not touch it, is to measure the distance between them. Here are two glass lenses, one of which is pressed against the other by means of a weight. By means of the electric light we may obtain on the screen an image of the place where the one lens presses against the other. A series of coloured rings is formed on the screen. These rings were first observed and first explained by Newton. The particular colour of any ring depends on the distance between the surfaces of the pieces of glass. Newton formed a table of the colours corresponding to different distances, so that by comparing the colour of any ring with Newton's table, we may ascertain the distances between the surfaces at that ring. The colours are arranged in rings because the surfaces are spherical, and therefore the interval between the surfaces depends on the distance from the line joining the centres of the spheres. The central spot of the rings indicates the place where the lenses are nearest together, and each successive ring corresponds to an increase of about the 4,000th part of a millimetre in the distance of the surfaces.

The lenses are now pressed together with a force equal to the weight of an ounce, but there is still a measurable interval between them, even at the place where they are nearest together. They are not in optical contact. To prove this, I apply a greater weight. A new colour appears at the central spot, and the diameters of all the rings increase. This shows that the surfaces are now nearer than at first, but they are not yet in optical contact, for if they were, the central spot would be black. I therefore increase the weights, so as to press the lenses into optical contact.

But what we call optical contact is not real contact.

Optical contact indicates only that the distance between the surfaces is much less than a wave-length of light. To show that the surfaces are not in real contact, I remove the weights. The rings contract, and several of them vanish at the centre. Now it is possible to bring two pieces of glass so close together, that they will not tend to separate at all, but adhere together so firmly that when torn asunder the glass will break, not at the surface of contact, but at some other place. The glasses must now be many degrees nearer than when in mere optical contact.

Thus we have shown that bodies begin to press against each other while still at a measurable distance, and that even when pressed together with great force they are not in absolute contact, but may be brought nearer still, and that by many degrees.

Why, then, say the advocates of direct action, should we continue to maintain a doctrine founded only on the rough experience of a pre-scientific age, that matter cannot act where it is not, instead of admitting that all the facts from which our ancestors concluded that contact is essential to action were in reality cases of action at a distance, the distance being too small to be measured by their imperfect means of observation?

If we are ever to discover the laws of nature, we must do so by obtaining the most accurate acquaintance with the facts of nature, and not by dressing up in philosophical language the loose opinions of men who had no knowledge of the facts which throw most light on these laws.

And as for those who introduce ætherial, or other media, to account for these actions, without any direct evidence of the existence of such media, or any clear understanding of how the media do their work, and who fill all space three and four times over with æthers of different sorts, why the less these men talk about their philosophical scruples about admitting action at a distance the better.

If the progress of science were regulated by Newton's first law of motion, it would be easy to cultivate opinions in advance of the age. We should only have to compare the science of to-day with that of fifty years ago, and by producing, in the geometrical sense, the line of progress, we should obtain the science of fifty years hence.

The progress of science in Newton's time consisted in getting rid of the celestial machinery with which generations of astronomers had encumbered the heavens, and thus "sweeping cobwebs off the sky."

Though the planets had already got rid of their crystal spheres, they were still swimming in the vortices of Descartes. Magnets were surrounded by effluvia, and electrified bodies by atmospheres, the properties of which resembled in no respect those of ordinary effluvia and atmospheres.

When Newton demonstrated that the force which acts on each of the heavenly bodies depends on its relative position with respect to the other bodies, the new theory met with violent opposition from the advanced philosophers of the day, who described the doctrine of gravitation as a return to the exploded method of explaining everything by occult causes, attractive virtues, and the like.

Newton himself, with that wise moderation which is characteristic of all his speculations, answered that he made no pretence of explaining the mechanism by which the heavenly bodies act on each other. To determine the mode in which their mutual action depends on their relative position was a great step in science, and this step Newton asserted that he had made. To explain the process by which this action is effected was a quite distinct step, and this step, Newton, in his "Principia," does not attempt to make.

But so far was Newton from asserting that bodies really do act on one another at a distance, independently of anything between them, that in a letter to Bentley which has been quoted by Faraday in this place, he says:—

"It is inconceivable that inanimate brute matter should, without the mediation of something else, which is not material, operate upon and affect other matter without mutual contact, as it must do if gravitation, in the sense of Epicurus, be essential and inherent in it. . . . That gravity should be innate, inherent, and essential to matter, so that one body can act upon another at a distance, through a vacuum, without the mediation of anything else, by and through which their action and force may be conveyed from one to another, is to me so great an absurdity, that I believe no man who has in philosophical matters a competent faculty of thinking can ever fall into it."

Accordingly, we find in his "Optical Queries," and in his letters to Boyle, that Newton had very early made the attempt to account for gravitation by means of the pressure of a medium, and that the reason he did not publish these investigations "proceeded from hence only, that he found he was not able, from experiment and observation, to give a satisfactory account of this medium, and the manner of its operation in producing the chief phenomena of nature." *

The doctrine of direct action at a distance cannot claim for its author the discoverer of universal gravitation. It was first asserted by Roger Cotes, in his preface to the "Principia," which he edited during Newton's life. According to Cotes, it is by experience that we learn that all bodies gravitate. We do not learn in any other way that they are extended, movable, or solid. Gravitation, therefore, has as much right to be considered an essential property of matter as extension, mobility, or impenetrability.

And when the Newtonian philosophy gained ground in Europe, it was the opinion of Cotes rather than that of Newton that became most prevalent, till at last Boscovich propounded his theory, that matter is a congeries of mathematical points, each endowed with the power of attracting or repelling the others according to fixed laws. In his world, matter is unextended, and contact is impossible. He did not forget, however, to endow his mathematical points with inertia. In this some of the modern representatives of his school have thought that he "had not quite got so far as the strict modern view of 'matter' as being but an expression for modes or manifestations of 'force.'" †

But if we leave out of account for the present the development of the ideas of science, and confine our attention to the extension of its boundaries, we shall see that it was most essential that Newton's method should be extended to every branch of science to which it was applicable—that the forces with which bodies act on each other should be investigated in the first place, before attempting to explain *how* that force is transmitted. No men could be better fitted to apply themselves exclusively to the first part of the problem, than those who considered the second part quite unnecessary.

Accordingly Cavendish, Coulomb, and Poisson, the founders of the exact sciences of electricity and magnetism, paid no regard to those old notions of "magnetic effluvia" and "electric atmospheres," which had been put forth in the previous century, but turned their undivided attention to the determination of the law of force, according to which electrified and magnetised bodies attract or repel each other. In this way the true laws of these actions were discovered, and this was done by men who never doubted that the action took place at a distance, without the intervention of any medium, and who would have regarded the discovery of such a medium as complicating rather than as explaining the undoubted phenomena of attraction.

THE TROGLODYTES OF THE VEZERE*

II.

WE have now examined the succession of prehistoric periods, from the beginning of the quaternary epoch, under the threefold aspect of stratification, palæontology, and archæology. We have thus obtained three series of dates, which do not always agree very strictly. They coincide only in the latest date, which marks the commencement of the modern epoch, and only approximate in the more ancient dates; but that is sufficient to enable us to arrange the following table, as a summary:—

	Stratigraphical Dates.	Palæontological Dates.	Archæological Dates.
Quaternary Epoch	Low level of the valleys undisturbed	Mammoth Age	Hatchet of St. Acheul
	Middle level	Intermediate Age	Moustier point
	Upper level	Reindeer Age	Solutré point
Modern Epoch	Recent soil	Present Fauna	Polished hatchet

Thus the Troglodytes of Perigord have existed in the two last periods of the quaternary epoch, from the decadence of the mammoth to the disappearance of the reindeer. It is impossible for us to measure the immense number of ages in which they lived, but we can have some idea of it by studying their stations in connection with the level of the Vézère.

Since the Moustier Cave has ceased to be inhabited it has so often been flooded by the Vézère that it has been entirely filled with alluvial earth. This layer of earth, nearly two metres in thickness, does not contain either bones or flint. It has covered the layer which was formerly the inhabited soil, in which man has left the tokens of his industry and the remnants of his feasts. This proves that the mouth of the cave was within reach of frequent floodings, and that consequently it was at a level hardly above that of the river. Now, at the present day, it is situated twenty-seven metres above the lowest watermark; the depth of the valley is therefore considerably increased since the epoch of the Moustier Troglodytes. On the other side, the station of La Madelaine, which is one of the most recent, perhaps *the* most recent of the valley, is very slightly above the level of the largest present floodings. We may hence conclude that the valley of the Vézère was very much then what it is now, and that since the epoch of La Madelaine the level has become lowered to the extent of a few metres only.

Thus this depression of twenty-seven metres, due to the action of the waters, was effected almost entirely under the eyes of our Troglodytes, and from that time, during the whole length of the modern epoch, that is in hundreds of centuries, it has made very little progress. Judge from this how many human generations must have come and gone between the epochs of Moustier and La Madelaine.

It is easy to see that in such an immense lapse of time the manners and industry of this people must have undergone notable changes. We shall have no trouble in proving this by the study of their different stations in succession.

II.—*Successive Stations of the Troglodytes of the Vézère*

We now possess the facts necessary to enable us to assign a place in chronology to the Troglodytes of the valley of the Vézère. There is not one polished hatchet to be found in their numerous stations; all their industry belongs to the epoch of hewn stone. They were therefore anterior to the modern epoch. They were acquainted with the mammoth; they fought him; they ate him; they even sketched him; they also knew the gigantic cave lion, and the cave hyena. Nevertheless, in their most ancient station—at least, the oldest with which we are acquainted, that of Moustier—the extinct species are already very rare. Our Troglodytes, therefore, do not date from the first quaternary period or Mammoth Age; but their station at Moustier belongs incontestably to the age which we have called intermediate, and which preceded the Reindeer Age.

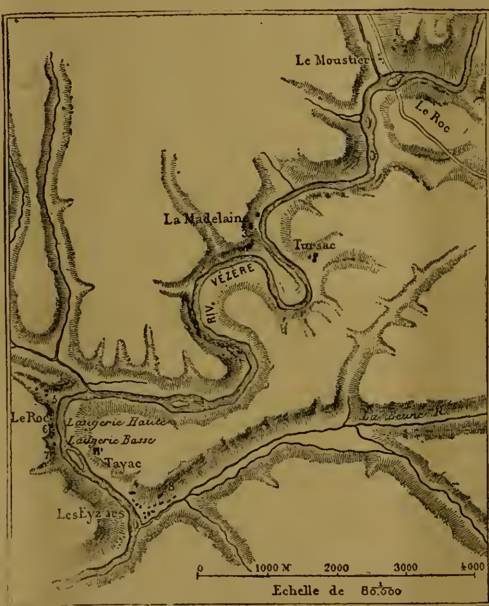

FIG. 8.—Map of the quaternary stations of the Vezère. 1.—Moustier cave. 2.—Moustier shelter. 3.—Shelter of the Madelaine. 4.—Shelter and burying-place of Cromagnon. 5.—Shelter of Upper Laugerie. 6.—Shelter of Lower Laugerie. 7.—Cave of the Gorge d'Enfer. 8.—Cave of the Eyzies.

Their other stations range from epoch to epoch until the end of the Reindeer Age; they therefore helped to destroy the ancient fauna. They did not, it is true, witness the disappearance of the last survivor, the mammoth, for some few rare vestiges of that animal are met with in the most recent caves of the Vézère, but at some leagues distance, at Excideuil, where MM. Jules and Phillippe Parrott have discovered a palæolithic cave in which was no trace of the extinct species, and in which even the reindeer was becoming rare.

All those of the stations that are known up to the present time are grouped on both banks of the Vézère in a very circumscribed space. From Moustier, which is up the river, to Eyzies, which is down, the distance is but eight kilometres as the crow flies; it is nearly double when you follow the windings of the valley. Between these extreme stations we see succeeding each other, on the right bank, those of the Madelaine, Upper Laugerie,

* Continued from p. 272

Lower Laugerie, the Gorge d'Enfer, then, on the left bank that of Cromagnon, very near the Eyzies (see the map).

Some are really habitable caves, others are simply shelters under the rocks, with large openings towards the valleys. But these distinctions have no chronological importance. It is not by the nature of the habitations, but by the nature of the *débris* they contain that we can estimate their relative antiquity. The stations at Moustier are evidently the oldest, that of Cromagnon is less ancient, but evidently belongs, like the preceding, to the intermediate age. Upper Laugerie, the Gorge d'Enfer, belong to the Reindeer Age; and finally Lower Laugerie, the Eyzies, the Madelaine, form a last group, and bring us to the end of the quaternary epoch.

The Moustier Troglodytes were quite uncivilised. They did not know how to fashion bones and horns; they only understood working in stone. Carved flints abound in their stations, but, with the exception of an arrow-point, rather carefully cut, all these flints are of very rough workmanship. The distinguishing weapon of the Moustier Troglodytes, that which characterises this station and epoch, is the lance or spear-point which we have already described (see above, Figs. 3, 4, and 5).

This powerful flint, with an arched point, sharp at both edges, wide enough to make large wounds, thin enough to penetrate easily into the flesh, constituted a much more terrible weapon than the hatchet of Saint Acheul. Fastened to the end of a spear, it could put to death the most gigantic mammalia. Vestiges of the mammoth, of the huge cave lion, and of the cave hyena have been picked up at Moustier. But the principal human food at that time was first the horse, then the aurochs; the reindeer came third. The weapons of the chase were more suited to attack the enemy that resisted than the game that fled. They neglected those lighter shafts that bring down birds and smaller quadrupeds. Fishing was also neglected and probably not known. There is not a single fish-bone or bird-bone in the Moustier stations.

FIG. 9. FIG. 10. FIG. 11.

Fig. 11.—Point in deer horn, without barbs (Gorge d'Enfer). Fig. 9.—Arrow with bilateral barbs. Fig. 10.—Harpoon with unilateral barbs.

The men of Cromagnon, less ancient than those of Moustier, had considerably advanced. Their implements

FIG. 12.—The Mammoth, carved on ivory. (Engraving from the Madelaine.

were less massive, more numerous, more varied, and, above all, better finished. They had not the Moustier point, but they had a kind of flint poignard. They wore shell ornaments, and their numerous scrapers seem to indicate that they prepared skins for clothing. Their principal food was still the horse, but they had a great variety. We find in the *débris* of their repasts, besides the reindeer, which was beginning to be plentiful, bones and teeth of aurochs, wild boar, stag, wild goat, wolf, fox, spermopile, hare, and even of a bird belonging to the Crane genera. They consequently hunted small game as well as large animals; but they were still ignorant of fishing.

Among these remains of animals we still find the mammoth and the great cave lion; likewise a large bear, which might well be the *Ursus Spelæus*. We must likewise remember that the reindeer had not begun to multiply rapidly, that it was less plentiful than the horse; we are therefore still in the intermediate age. But, on arriving at the following stations, we enter definitely the Reindeer Age; henceforward the vestiges of this animal

will be more abundant than those of all the others put together.

The finest works in flint of the Valley of the Vézère are those of Upper Laugerie. All the implements, all the weapons of that station are in flint. They are innumerable; their shapes and dimensions are very varied. Side by side with imperfectly fashioned objects we find others whose elegant form and delicately finished contours reveal accomplished workmen.

These beautiful flints of Upper Laugerie belong to the Solutré type. Their shape is lanceolated; they are not thick; their graduated edges, jagged with little notches, are regular and symmetrical; their base is often fashioned so as to facilitate putting on a handle. They are evidently destined to be adapted to the extremity of a piece of wood. Their dimensions vary considerably; the shape is much the same. It is easy to see that the small ones are arrow-points; the medium size doubtless furnished the darts which were hurled from the hand. The largest are lance-points, but their want of width shows that those lances were rather light.

These carefully-wrought points, so common at Upper Laugerie, are not to be found in the later stations of the valley of the Vézère. It was surmised, from this circumstance, that the workmanship of flints, after having progressed till the time of Upper Laugerie, had then declined. This caused surprise, and justly; for it would be astonishing if such an intelligent people, as were evidently the Troglodytes of the Reindeer Age, had allowed their main branch of industry to decay. But many objects found in their more recent stations prove that they had not lost the secret of fine carving; and that, if they no longer wrought the points of Upper Laugerie, they no longer needed them.

A great progressive stride had been accomplished. They had learned how to shape the deers' horns, and the bones of animals. It was with those substances, more pliable than flint, less hard, no doubt, but quite solid enough to fabricate darts and arrows of a longer flight and a greater precision. Then, when these modes of workmanship were once known, the bones and horns of deer were used to manufacture a vast number of tools and utensils of every description.

But, for all that, the reign of flint was not over. On the contrary, the varied assortment of cut flints was greater than ever; to those which served as weapons and implements were now added a multitude of small tools destined to use for working the deer-horn.

We have here arrived at an important evolution of industry. Up to that time there had only been simple industry, or as it were primitive, utilising the original substance direct. Now we come to progressive industry. Tools were manufactured whose sole use was to fabricate others.

In all ages flint had been employed as an instrument of workmanship. From the commencement of the Stone Age it had been used to cut the horn, to make pikes, clubs, handles of lances or darts. The idea of making use in the same manner of the bones of animals was not new either, for in the ancient station of Cromagnon were found some dart-points of deer-horn, and even some pieces of ivory. But the characteristic feature of the epoch on which we are entering was the creation of special tools which were not necessary for the wants of life, and which were destined to facilitate and perfect the fabrication of useful implements. From that time commenced that division of labour which, in a future day, was to increase a hundredfold the power of man and subject all nature to his sway.

The workmanship in deer-horn was already pretty far advanced in the station of Gorge d'Enfer. We find there a complete assortment of objects in this substance—lances, darts, arrows, bodkins, needles, hunting marks, account registers, &c. These articles are pretty well wrought, but without ornaments, and the darts are of the simplest shape. They are conical points, without any barbs. (See Fig. 11.)

The invention of barbs is worthy of attention. These recurring points no doubt rendered the blow more dangerous; the projectile remained fixed in the flesh, and the wounded animal could not get rid of it as he fled through the bushes. But this was probably not the principal object of the barbs. Placed in a regular series on both sides of the arrow (see Fig. 9), they sustained it in the air like wings; they increased the flight and the precision of the aim, and this innovation suggests a certain knowledge of experimental physics. The barbs are generally provided on one side with one or more openings, which are supposed to be destined for the reception of poison. The barb of the arrows and the ornamentation, more or less artistic, are the two distinguishing marks of the stations of the latest epoch. These are three in number—the Eyzies, Lower Laugerie, and the Madelaine. They resemble each other closely, and it is probable that they were nearly contemporary.

III. *The Society of the Troglodytes*

The caves of the Troglodytes were situated near the Vézère, without any special aspect, excepting perhaps that they were never open to the north.

They lived in them the whole year round. This is proved by the remains of their food, for they ate the reindeer fawn of every age. An examination of the teeth of these young animals, of their bones, of their horns in different stages of growth, enables us to determine the number of months they had lived, and consequently the season of the year in which they were killed. Hence we may aver that our Troglodytes had a fixed residence, in other words, that they were not nomads.

When they went out fishing or hunting they closed the mouth of their caves to prevent the entrance of carnivora. A single bone, found at the Madelaine, has the trace of a hyæna's teeth. This animal may have once by accident gained an entrance. The hyena was rare at that epoch, but wolves and foxes were numerous, and if they did not come and gnaw the bones scattered all over the floor of the cave, it was because the latter was carefully closed. As there is no vestige of a stone door at the approach to our caves, the Troglodytes, doubtless, closed their doors with palisades.

There have certainly been found, in the three stations of the latest epoch, a certain number of stones in granite, sandstone, or quartz, rounded and polished nearly smooth with friction, presenting on side a very regular depression in the form of a little cup, and resembling little mortars. From this has arisen the supposition that the Troglodytes ground corn for food; but all concur in proving that they did not understand agriculture. It is much more probable that they used their mortars to triturate poisons or colours.

Hunting was their chief resource and occupation. The remnants of bones accumulated on the floor of their caves prove that they hunted animals of every size, from the small bird to the mammoth. This old giant of the early quaternary age still survived, but he was becoming very rare.

Here is the representation of a piece of ivory discovered in 1864, at the Madelaine, by MM. Ed. Lartet, de Verneuil, and Falconer. On this surface, an engraved drawing represents the mammoth, with his head erect, his brow concave, his great tusks bent, his small eye, his long trunk, his tail elevated, and his long mane. In a word, precisely like the mammoths in flesh and bones, which a perpetual frost has preserved to our own days on the banks of the Lena. (See Fig. 12.)

The Troglodytes of the Reindeer Age had rarely an opportunity of encountering the mammoth. They more frequently hunted the aurochs, the horse, the ox; and it was doubtless for hunting these large animals that they still

had some large spears, armed with flint, differing little from those of Moustier. But nearly all their weapons were light, and the deer-horn points replaced the flint points of an earlier epoch.

The bow had become the predominant weapon, for henceforth nothing resisted man; all fled before him, and hunting was no longer a struggle but a chase. There were two kinds of arrows: the little pointed arrow, not barbed, for small animals and birds, and the large dart with two sets of barbs, which was principally used in hunting the reindeer. Light spears, terminating in a flattened point, darts with conical points, and long sharp poignards, which gave, when necessary, the finishing blow, completed the hunting equipment. I was nearly forgetting the rallying whistle. It was a reindeer's phalange, pierced near one end, with an oblique hole which did not go right through, and only penetrated to the medullary canal. By blowing on this hole as on a drilled key, one can, even to this day, extract shrill sounds.

(*To be continued.*)

THE NEW HYDROCARBON GAS

THE new hydrocarbon gas produced by Mr. Ruck's process certainly promises to realise the conception that has long floated in the minds of scientific men of turning the exhaustless store of heating power to account that lies ready to hand in water. Mr. Ruck appears literally, by the successful development of his invention, to have set the Thames on fire. At this present time, at the Battersea water-works, on the banks of the old river, near to Battersea Park, both light and heat may be seen and felt in the process of evolution from the decomposition of the water of its stream, and further light is added to the gas first produced by a very simple and uncostly extension of the process, until the illuminating power is raised to the intensity requisite for artificial lighting during the dark hours of the night. The Battersea water-works are now lit experimentally by this new form of gas, an apparatus having been erected there to test and prove the efficiency and value of the method.

Mr. Ruck's hydrocarbon gas, it should be at once understood, differs entirely from the so-called "air gases" that consist mainly of air impregnated with the vapour of some form of naphtha or petroleum, in the fact that its base is essentially a gas. The heating gas, which is the form first generated, is true honest hydrogen mingled with a little taint of carbonic oxide, and a small and practically unimportant percentage of carbonic acid; and the apparatus by which this heating gas is produced is remarkably ingenious and simple. Ordinary steam is brought through a pipe from one of the boilers of the engine house, and this steam is poured through a horse-shoe-shaped tube that passes through the red heat of a fierce coke furnace. In this tube it is superheated, or raised to a temperature which disposes its constituents, the oxygen and hydrogen, to dissolve their intimate alliance, and in that state it is passed on into retorts, also contained in a lower region of the same furnace, which are packed full of coke and fragments of iron. The steam is discharged into the interior of these retorts out of its own conducting pipe, so that it has to traverse their entire length amidst the masses of heated metal and coke, and during its journey it ceases to be steam. The oxygen attaches itself to the iron, and forms scales of black rust, and the hydrogen passes on free, with only a commingling with carbonic oxide and carbonic acid formed by the action of the disengaging oxygen upon the coke packing of the retort, and with certain sulphurous vapours that also issue from the coke. In this impure state the gas issues from the retort, and is carried to a purifying chamber containing oxide of iron, which at once clears it from all the sulphur compounds, and it is then stored in a gas reservoir of ordinary form. In this state it is the "heating gas;" that is, gas supereminently suited for all purposes where heat, without light, is required, as, for instance, for gas stoves of whatever kind, or for boiling water, and generating steam. When the gas is taken from this reservoir, and discharged through an ordinary burner, it burns with the pale colourless hydrogen flame, streaked with a few lines of yellow scintillations, and of the characteristic pale green colour of incandescent carbonic oxide.

At the present time, with coals quoted in the London markets at 52*s.* per ton, this part of the affair, the production of a heating gas out of water, at the cost of a very simple apparatus, a very small consumption of fuel, and with a demand for an incredibly small application of manual labour, seems to be the one that is most deserving of thought and attention. In the practice of the manufacture at the Battersea water-works, by the expenditure of one ton of coke for the interior of the retorts, and of two tons of coke for the support of the heat of the furnace, 133,000 cubic feet of gas are produced, that, to say the least of it, is quite equal for all purposes of heating to coal gas in ordinary use, and that is as chemically enduring and perfect for storing in gasometers and for transmission to unlimited distances through pipes. In a direct experiment with the gas, tried by the writer, one quart of cold water was boiled in four minutes and a half by a jet of flame issuing from an orifice one-eighth of an inch in diameter, and under a pressure of three inches of water, without any arrangement for the concentration and protection of the flame from chill and draughts. There was no provision on hand to measure the exact consumption of the gas, but the man who was engaged in the Laboratory estimated it at about five cubic feet per hour. Now the cost of this gas at the works is found to be 7*d.* per 1,000 cubic feet. In this experiment, therefore, the result was something like converting seven gallons of water at a temperature of 38° Fahrenheit, into boiling water for 1*d.* One thousand cubic feet at a cost of 7*d.* would boil about 50 gallons of cold water. At the works at the present time the steam is supplied independently from the boiler of the engine room. But this does not need to be taken into consideration, because the waste heat of the retort furnace is more than enough for the production of the steam, and in ordinary circumstances will be used, as a matter of course, for the purpose.

When it is desired to use the gas for lighting purposes, it has to be further prepared and manipulated. The "heating gas" from the gasometer is made to bubble through a reservoir containing rectified petroleum at a specific gravity of about 0·680. It then passes at once into the pipes for circulation and consumption, and issues from these burners a very excellent gas, equal in illuminating power to 16½ candles with a consumption of 5 cubic feet an hour in an Argand burner. The cost of the gas in this form is a trifle less than 1*s.* 8*d.* per 1,000 cubic feet, and the saving in the manufacture over ordinary coal gas with coals costing 26*s.* per ton, is estimated to be 40 per cent.—in exact figures 1*s.* 8*d.* per 1,000 cubic feet against 2*s.* 4*d.* per 1,000 cubic feet. One thousand cubic feet of the heating gas require a gallon and a half of the petroleum to convert them into illuminating gas, but they are considerably increased in volume by the conversion—133,000 cubic feet of "heating gas" become 165,000 cubic feet of "illuminating gas" after it has been passed through the petroleum. Arrangements have been made for the purchase of several millions of tons of crude petroleum at a price which will represent a cost of 6*d.* a gallon after rectification.

Some rather severe experiments have been already tried to test the power of the illuminating gas to retain its full charge of carbon after travelling through long distances of delivery at low temperatures, and the report of the testing engineers is that so far the experiment was

eminently satisfactory, and that there was no perceptible loss of illuminating power. Experiments on this point, however, and also upon the arrangements that will best enable the heating gas to be turned to account, are still in progress, and will afford ground for further notice in due time.

The furnace and retorts which are at work at Battersea are very compact, occupying about the space of an ordinary well-packed steam engine of 20 or 30 horse power. These retorts however are only in use for about two hours out of the twenty-four to supply the works with illumination, and it is estimated that they would be quite large enough to supply illuminating gas for the consumption of a small town of about 4,000 inhabitants. As regards the most important bearing of saving of manual labour it is found to amount to dispensing with the services of 29 labourers out of every 30 who are required in the old process of coal distillation. The charge of coke and iron which is now in the retorts yielding the gas at Battersea has not been changed, or renewed, for several weeks. The iron in the retorts is in the form of old chain, for the convenience of withdrawal, and seems to cover itself with thin black scales. The carbon in the interior of the retort is removed entirely by the gas as it is gradually converted in the process of manufacture into carbonic acid and carbonic oxide.

It may, perhaps, be well to remark that a process for the manufacture of "water gas" was presented by M. Gillard some fourteen years ago, in which superheated steam was decomposed in retorts by the action of incandescent charcoal; the carbonic acid, so formed, issued from the retort with the hydrogen, and was afterwards removed in a special purifier. Lighting power was secured by heating platinum wire in the flame. The distinctive features of Mr. Ruck's process are—the decomposition of the superheated flame by coke and iron, which remain long periods in the retorts without change; the removal of sulphur products by oxide of iron; and the carbonising for illumination by passing the hydrogen through rectified petroleum.

HUNTERIAN LECTURES BY PROF. FLOWER

LECTURES I. II. III.

IN considering the various formations which compose the earth's crust, it is unnecessary, whilst speaking of the mammalia, to refer to rocks lower than those of the secondary formation, for no palæozoic mammals are known. Respecting the value of palæontology in supporting or disproving the various theories at present in vogue regarding the origin of life, the details of the course will supply evidence of value. The amount of "the imperfection of the geological record" will be demonstrated in the classes considered. The extreme unlikelihood of any aërial animals being preserved in the fossil state is scarcely realised by many, nor is the smallness of the extent of the surface of the earth which has been examined. An accidental discovery like that in the upper oolite, of an extremely small deposit containing numerous marsupial remains, has done more to throw light on the subject than many more painstaking researches over larger fields. These facts being taken into consideration, it is clear that if it can be shown that the examination of fossil remains indicates only a tendency towards the filling of the gaps between existing groups, the tendency will be strongly in favour of evolution; but if it brings to light nothing but types which are entirely new, the doctrine of special creations will be supported. Prof. Huxley has been able to show many of the transitions between reptiles and birds, and Prof. Marsh's new discovery of *Odontornis* is an important addition. It is among mammalia that in the present state of our knowledge there are the greatest gaps. The relations of the Cheiroptera are indeterminable, and so are those of the Edentata; not much is known of the Cetacea as regards their affinities, though they may be near the seals on the other hand. The Ungulata constitute a group in which the considerable gaps between existing types are almost completely removed by the study of fossil forms. Taking first the Perissodactylata, in the Pliocene, Equidæ abounded in America as well as in the Old World. Tapirs and Rhinoceroses were equally abundant; these are the remnants of a large group which is probably becoming extinct, as it is indicated by the fact that the species are becoming less numerous. A little further back we find Hipparion with rudimentary side toes. In the Miocene and upper Eocene, Anchitherium and Palæotherium represent the group, though the latter is peculiar in its teeth. Fossil Rhinoceroses have larger teeth and no horn, some possess incisors, and the other teeth less specialised. The Tapir stands much by itself, and an ancient type containing Lophiodon and Hyracotherium seems to be now unrepresented. Again, among the Artiodactylates, *Chœropotamus* and *Hyopotamus* as far back as the Eocene are the most generalised, and from them as we ascend in the series the differentiation towards existing types becomes more and more evident. Among these later forms the North American *Oreodon*, which has been obtained in such great numbers, tends to the ruminants, but possessed upper incisors and canines. The Miocene of France and Germany affords very similar evidence. It is also interesting to note that the further we go back, the more do the individuals of the Perissodactylate group approach the Artiodactylates, but as yet no connecting link has been obtained. The Proboscidia, animals first appearing in the Miocene, approach in the older forms to the Ungulata, and Prof. Marsh's newly discovered Dinoceras seems to help to fill the gap.

In reviewing the various strata which are found to contain remains of mammalia, those of the quaternary or post-pliocene period are rich in species not far removed from existing forms. In most countries where limestone rocks exist, caverns are found containing large numbers of bones, such as those of Kirkdale, Liege, and Gibraltar, the last having been lately explored by Mr. Busk. Those of the Wellington Valley in Australia have afforded numerous remains of marsupials, showing that those animals have been located there for a considerable period. Again from the Pampas of South America many of the valuable skeletons which enrich the collection of the College of Surgeons have been obtained. The Miocene formation is particularly interesting from the richness of its fauna. *Dinotherium* and *Mastodon* being obtained in South France, as well as at Pikermé in Greece, where they are associated with *Hipparion*, the giraffe and others. Belonging to the same formation are the strata of the Siwalik Hills of India, which abound in hoofed animals, and have been so well worked out by Dr. Falconer. The peculiar mammalia of the territory of Nebraska, at the foot of the Rocky Mountains, belongs to the same age. In the Eocene period lived the animals so fully described by Cuvier, *Palæotherium*, *Anoplotherium*, &c. Besides in the Paris basin, similar strata occur at Hordwell, in Hants, and at Binstead, Bembridge, and Headon, in the Isle of Wight. In the London Clay of Sheppey *Hyracotherium* and *Lophiodon* are found.

Early in this century, it was supposed that mammalia were not present in the secondary rocks; but this was shown to be incorrect. In 1847, Prof. Pheninger discovered in some Triassic sand he was sifting a minute tooth with double fangs, probably belonging to some marsupial animal, which he named *Microlestes*. Prof. Owen considers it to be related to *Myrmecobius*. Similar teeth from the Rhaetic beds have been discovered by Mr. C. Moore, of Bath. An equally minute Triassic tooth was found by Mr. Boyd Dawkins at Watchet, in Somersetshire, and from its slight resemblance to that of *Hypsiprymnus* it has been named

Hypsiprymnopsis. Among the coal-fields, probably of the Trias Age, in North Carolina, the late Prof. Emmons obtained the lower jaws of three insectivorous or carnivorous animals, with the following dental formula — i. 3, c. 1, p.m. 3, m. 7, and, as Prof. Owen has pointed out, this large development of the molar series approximates it to *Myrmecobius*. A peculiarity of these jaws, as of all others from the secondary formations, is that a long groove runs along their inner side in the position of the mylo-hyoid groove of recent mammals; this is only a result of arrested development round Meckel's cartilage, and it does not indicate—as has been supposed by some—reptilian affinities, there not being any signs of more than two centres of ossification. So early as 1812, a man working in the Lower Oolite of Stonefield found a perfect lower jaw one inch long. This was taken to Mr. Broderip and Mr. Buckland; Cuvier also had an opportunity of seeing it, and called it an opossum. Dr. Blainville thought that it was reptilian, and called it *Amphitherium*. Owen clearly proved that it was marsupial, the angle being inflected. The dental formula is i. 3. c. 1, m. 12, and the shape of the teeth indicates an insectivorous or carnivorous diet. *Phascolotherium*, another genus from the same slates, has the formula i. 3, c. 1, m 7, which, if it had one more incisor, would be like that of the opossum. Higher up in the secondary formation, in the Purbeck, Mr. Brodie obtained several small jaws from Durdlestone Bay, near Swanage. Mr. Beccles thoroughly explored this bed, and very valuable results have been obtained, more than forty jaws, nearly all lower, of twenty-four species belonging to ten genera, having been described by Owen.

NOTES

By five decrees of the French government, dated February 13, the working of the French observatories has been thoroughly reorganised, and if the new system is faithfully carried out, we have no doubt it will be productive of good results. The management of the government observatories is entrusted to a body of astronomers responsible to the Minister of Public Instruction, and consisting of titular astronomers (*astronomes titulaires*), associate astronomers (*astronomes adjoints*), and assistant astronomers. This *personnel* is distributed among the various observatories according to the requirements of the service, and the special resources offered by each establishment for the researches of observers. The staff of the observatory of Paris consists of a director, six titular astronomers, ten associate astronomers, and several assistants. A responsible secretary is attached to the establishment. The Paris observatory has a scientific council, composed of the director, the various chief astronomers of the service, and of six councillors of the observatory, chosen from among scientific men eminent in mathematics, astronomy, or physics, and of whom four at least must belong to the Academy of Sciences or to the Bureau des Longitudes. These are to be nominated by decree, in accordance with the advice of the Council, and upon the proposal of the Minister. The Council is to meet once a month, and every year, at Easter, the directors, the councillors, and the chiefs of the various scientific establishments, meet in general assembly with the Minister of Public Instruction. The directors and the titular astronomers are appointed by the President of the Republic, acting according to the advice of the General Assembly. The salaries of the titular astronomers vary from 6000 to 8000 francs, those of the associate astronomers, divided into three classes, from 3,500 to 6,000 francs, and those of the assistant astronomers, also divided into three classes, from 1,000 to 3,500 francs. These salaries do not strike us as being particularly liberal. By a second decree, M. Le Verrier has been made Director of the Paris Observatory; the Councillors of the Observatory are, MM. Belgrand, Fizeau, Vice-Admiral Jurien de la Gravière, Janssen, Tresca, Daubrée; and Members of Council, MM. Yvon Villarceau, Wolf, Gaillot, and Rayet. M. Marie Davy is appointed Director of the Meteorological Observatory of Montsourris, and M. Stephan of the Observatory of Marseilles.

The arrangement of the buildings in which the Annual International Exhibitions are held, makes it almost essential for their success that visitors should be able to pass from one side to the other across the gardens of the Royal Horticultural Society. A large body of the Fellows, however, more especially those residing in the neighbourhood, object to the admission of the exhibition visitors, as an infringement upon the privacy of the gardens. At the late adjourned annual meeting there was a very stormy discussion upon the subject, and the report of the Council recommending a continuance of the policy of meeting the views of the managers of the exhibitions was rejected by a large majority. The Council thereupon expressed their intention of resigning; but this, it appears, they have no legal power to do till the expiration of their term of office.

Captain M. F. Maury, the well-known American hydrographer, died on February 1, at Lexington, Virginia, at the age of sixty-six years.

The *Times* announces that the Council of the Royal Society are about to nominate Dr. Hooker as President of the Society, in succession to Sir George B. Airy, who retires from the chair at the Society's anniversary in November next.

It is announced in a "cable" telegram from America to the Astronomer Royal, that a new planet (130) was discovered by Peters on February 18. It is of the eleventh magnitude, and was moving rapidly towards the north. R. A., 10h. 0m., Decl., 13° 40′ N.

Mr. T. M'Kenna Hughes, M.A., of Trinity College, has been elected Woodwardian Professor of Geology at Cambridge, in succession to the late Prof. Sedgwick. Originally there were nine candidates, but most of them retired before the poll, and the real contest lay between Mr. Hughes and Mr. Bonney, a Senior Fellow of St. John's, the numbers at the close being 112 and 105 respectively.

By a resolution of the Board of Trinity College, Dublin, the Natural Sciences have been introduced into the Undergraduate Course. Hitherto a student might select the Natural Science Course for his final examination in Arts, obtaining a senior or junior Moderatorship, according to his answering; now having once passed his "little go," the student may in his third year select for his term Lectures and Examinations, Botany and Zoology; and in his fourth year Physical Geography and Palæontology. For this purpose the following courses of lectures have been arranged:—Michaelmas Term—Prof. Haughton, M.D. F.R.S., lectures on Physical Geography; Prof. E. Perceval Wright, M.D. on Histological Botany; Prof. Macalister, M.D. on Vertebrata. Hilary Term—Prof. Haughton on Palæontology; Prof. Wright on Cryptogamia; Prof. Macalister on Mollusca and Arthropoda. Trinity Term—Prof. Haughton on Palæontology; Prof. Wright on Phanerogamia; Prof. Macalister on Annulosa, Cœlenterata and Polyzoa. In addition, in Trinity Term, Demonstrations are given by the several Professors in Palæontology, Comparative Anatomy, and Botany.

At the Fellowship Examination at Trinity College, Cambridge, in 1874, a Fellowship will be obtainable by adequate proficiency in Natural Science. The Examination, which will take place in the end of September or the beginning of October, will be chiefly in Chemistry, Physics,

and Biology, and in the subjects of any papers which may have been sent in. Candidates are invited to send in to the Examiners (care of Mr. Trotter), on or before May 15, 1874, any papers which they may have published containing original observations or experiments, or discussions of scientific questions, or any similar matter in manuscript. The papers may be on any branch of Natural Science which is not strictly medical. They must be accompanied by a statement as to what portions of the matter are claimed as original, and of the sources from which the rest is derived so far as they are not explicitly stated in the paper itself. Candidates will be liable to be examined in the subjects of their papers, and in matters connected with them, or in the branches of science to which they refer. This Fellowship will be open to all Bachelors of Arts, Bachelors of Law, and Bachelors of Medicine of the University, whose standing after their first degree does not exceed three years. Candidates who are not members of the College must send their names to the Master on or before September 15, accompanied by certificates of good character. For further information, apply to the Rev. Coutts Trotter, Tutor of Trinity.

M. René de Brebisson writing under date of February 16 to the Secretary of the Dublin Microscopical Club, mentions that while the smaller collections of Algæ belonging to his late distinguished father, had for some time past been disposed of, yet the large collection of Diatomaceæ was still for sale. This collection contains (1) 8,000 prepared slides, some in fluid, but the greater part by far in Canada Balsam; (2) about 600 tubes and bottles of Diatoms in alcohol ready for mounting; and (3) a collection of Diatoms on mica and some few n paper. These collections contain the types of most of the species described by De Brebisson, Kutzing, Smith, Ralfs, Grunow, W. Arnott, De Notaris, &c. &c. The price asked is 10,000 francs, but possibly for a public collection 8,000 francs might be taken. The collection is well worthy the attention of botanists, and we hope soon to be able to report that it has been disposed of.

The Royal Dublin Society has inaugurated a course of lectures on subjects connected with public health, in the arrangement of which the Dublin Sanitary Association afforded its advice and assistance; the first of the series, being Introductory, was delivered on Saturday, Feb. 22, by Dr. W. Stokes, F.R.S., and the remaining ten will be delivered each Saturday until completed. The Subjects and Lecturers are as follows:—On the discrimination of Unadulterated Food, by Dr. J. Emerson Reynolds. On Meteorology in its bearing on Health and Disease, by Dr. T. W. Moore. On the Geographical Distribution of Disease, by Dr. T. Little. On Zymotic and Preventible Diseases, by Dr. T. Grimshaw. On liability to Disease, by Dr. Alfred Hudson. On Antiseptics and Disinfection, by Dr. R. Macdonnell, F R.S. The Prevention of Artisans' Diseases, by Dr. E. D. Mapother. On the Contagion Theory of Epid mics, by Rev. Dr. Haughton, F.R.S. On the Construction of Dwelling Houses, with reference to their Sanitary arrangement, by Mr. G. C Henderson; and on Sanitary Legislation, by Mr. R. O. B. Furlong.

We understand that the delay which has occurred in the issue of the volume of the *Zoological Record* for 1871, has been caused by the illness of one of the contributors to the Invertebrate section. At a recent meeting of the Council of the Zoological Record Association it was determined to issue the portion of the volume already completed (down to the end of the Insecta) immediately, leaving the remaining section until the health of the contributor allows of its completion.

Prof. Giglioli, of Florence, has lately re-examined the skull of the Chimpanzee of East Africa, which was obtained some years ago from the Upper White Nile, and was formerly in the Museum of the School of Medicine of Cairo, and has come to the conclusion that it belongs to a new species which he proposes to call *Troglodytes Schweinfurthii*, after the well-known African traveller of that name.

The Royal Zoological Society of Ireland has just issued its forty-first annual Report. It would appear that the Gardens were visited during 1872 by 147,184 persons, being nearly 20,000 less than 1871; but this is abundantly accounted for by the extreme wetness of the past year. Perhaps the most interesting addition to the Garden during that period consisted of two living specimens of the Climbing Perch of India (*Anabas scandens*); these were presented by Staff-Surgeon Dobson of Calcutta.

We have received from Mr. Roosevelt, the secretary, the third and fourth annual Reports of the American Museum of Natural History, from which we learn that this newly founded national collection, situated in Central Park, New York, is being conducted with an enterprise and discretion which, if continued, will shortly render it worthy of the capital it represents. Frequently during the last year it was visited by more than 10,000 people in one day, and every encouragement is given to students of science. Among the most valuable donations during the last two years is a great Auk, presented by Mr. R. L. Stuart, and a large collection of insects from Madame Verreaux, of Paris.

Prof. Tyndall arrived at Liverpool on the 19th inst., in the *Cuba*.

At Thorn, in Prussia, where he was born in 1473, the four hundredth anniversary of the birthday of Copernicus was celebrated on February 19. Speeches were delivered by several scientific men, and a ball was given in the town hall.

According to the accounts we have as yet seen of the Samos earthquake it was of a remarkable character. It affected chiefly the pretty little capital of Vathy. The shocks were not felt throughout the island, but only on the coast between Kotzika and Pagonda. Nevertheless a counter shock was felt as far off as Smyrna. So far as we can make out, the first shock, which was the strongest, was felt at 1 A.M. Up to Feb. 3, 104 shocks had been felt at intervals, 4 or 5 very strong and threatening.

The Smyrna earthquake was on Feb. 1 or Jan. 31 at night, and was violent. The oscillation is reported as from S.W. to N.E.

The weather in Yanina, in Epirus, up to the beginning of February, had been most remarkable. There had been great rains, and the fruit trees had already yielded fruit. In the neighbouring provinces of Bosnia and Prizrend the fruit trees had also blossomed in full winter, and some had given fruit. The like is reported from Verzin, where plum trees, pears and figs had produced fruit of good quality.

A coal mine has been discovered in the Bagdad district between Yezireh and Zeto. According to the report of M. Mougel, engineer to the viceroyalty, the formation extends over a length of more than four miles with a breadth of from 400 to 450 feet. About 84 tons were got out in the first three weeks.

We have received from Dr. Petermann a beautifully executed map of South-west Germany, with Alsace and Lorraine as they existed before the outbreak of the French Revolution in 1789.

We learn from the *Times of India* that the Bombay Geographical Society has been formally amalgamated with the local branch of the Royal Asiatic Society.

We learn from the *Garden* that an American has made an experiment with the view of ascertaining how far soil is protected from cold by snow. For four successive winter days, there being four inches of snow on a level, he found the average temperature immediately above the snow 14° below zero; immediately beneath, 10° above zero; and under a drift 2 ft. deep, 27° above zero.

PROFESSOR RAMSAY ON LAKES*

II.

III.—*The Waters of the Cambrian and Silurian Epochs and the Lakes of the Old Red Sandstone*

THE lecturer first briefly summarised the reasoning and the conclusions contained in his two preceding lectures on the origin of fresh and salt water lakes, and then proceeded to apply them to explain certain phenomena of the above geological epochs as deduced from the rocks belonging to those periods. He was about to endeavour to prove that certain of the formations included in a table of the stratified rocks were not formed in the open sea as usually supposed, but were formed in great lakes. The small numbers of fossil shells found in fresh-water strata and in some cases their total absence rendered absolute demonstration very difficult. The Cambrian strata, seen in England, in North Wales, Shropshire, and other parts consist of red and mottled sandstones and slates, and contain but few fossils; trilobites and one or two fossil shells have been found, not in the red strata, however, but in blue and grey shades. Above these the Lingula flags (a member of the Lower Silurian) contain fossils in great numbers, and of such creatures as must have lived in the open ocean of that period. In the Upper Silurian, too, fossils are very numerous, and all inhabitants of the sea. But above these, in the Old Red sandstone, the numbers have declined both in genera and species and individuals, and the shells, &c., which remain are small and dwarfed in size. Yet the strata of the Old Red sandstone lie conformably on the Upper Silurian, showing that the passage from the one set of beds to the other was gradual, and the change in the fossils is likewise gradual.

The Old Red strata consist of red sandstones (forming about two-thirds of the whole strata) and a red marl developed in England, in South Wales, Herefordshire, &c., throughout the whole of these strata fossils are very scarce, chiefly occurring in the uppermost and lowermost portion. In the Ludlow rocks, at the upper portion of the Silurian strata, are found fragments of stones and seed vessels of land plants for the first time. Not that land plants did not exist before that period; the lecturer thought they had done so, but that their remains were not preserved in the rocks, inasmuch as they had been formed in the open sea, far from land. But their occurrence in the Ludlow rocks evidently proves that those strata, although truly marine, were formed in the neighbourhood of land, and, as the lecturer believed, in waters more or less land-locked. These passage beds also contain the remains of fish of various genera—Cephalaspis, Onchus, &c. But passing upwards into the beds of the Old Red sandstone, the fish which occur have their nearest living analogies in inland fresh-water areas; *e.g.* the Lepidosteus of the North American rivers, the Polypterus of the Nile, and the recently discovered Ceratodus in the rivers of Australia. Large crustaceans—Eurypterus and Pterygotus—occur higher up in the formation, and in all cases where they are found, and in the majority of cases where fish are found in these strata, shells are not associated with them. Hence from the absence of shells, and their dwarfed forms when they do occur, especially as compared with the underlying Silurian beds, and from the presence of those peculiar kinds of fish, we are entitled to infer that the strata were deposited in inland lakes. Again, examination of a piece of the red sandstone will show it to be composed of a number of minute grains, each surrounded by a thin pellicle of peroxide of iron, to which the red colour of the rock is due, for when this iron is discharged by chemical means the rock remains purely white. All truly marine rocks that we know are in no case coloured red; they are black, blue, green, or yellowish, but never red, and there is no reason why in the sea iron should be deposited as a peroxide. But in certain lakes in Sweden there is a constant deposit of iron oxide; and though this is due to organic agency, still it occurs in lakes, but never in the sea. The Old Red sandstone is not a wide-spread formation, but has more of a local character.

The lecturer then showed by means of diagrams how he conceived that certain areas of the Silurian seas might be isolated and shut off from the ocean by elevation and depression of the land, that the gradual freshening of these inland areas would result in dwarfing and deforming the marine creatures in the waters, and rendering them gradually extinct. The lakes in the north of Europe, which must have been filled with sea-water just after the glacial epoch, are similar cases, for in some of them the marine forms are not yet totally extinct, but have become partly acclimatised, and so the occurrence of a few such forms in these rocks is no conclusive evidence against their being formed in inland and fresh-water lakes, but rather the contrary. At the top of the Old Red sandstone beds land-plants and fresh-water shells occur. In the north of Scotland the Old Red sandstone rocks are well developed, the Grampians at that time standing out of the waters. The bottom bed is a clay with angular boulders, much resembling the "boulder clay" formation, and evidently of glacial origin, and though the lecturer dare not assert that glaciers scooped out the lakes in which the rocks were deposited, still it was very interesting to have evidence of their connection with those lakes. He likewise pointed out that if this theory of the lake origin of certain formations, first suggested by Mr. Godwin Austen, were established, it would open out an entirely new field of geological research by revealing to us the conditions not only of the ancient seas, but also of old continental areas.

IV.—*Salt Lakes of the Permian Epoch*

Prof. Ramsay first explained that it was necessary, in attempting to demonstrate the truth of his assertions as to certain formations having been deposited in inland waters to commence by considering the conditions of the preceding epoch, and trace the gradual change in the deposits resulting from the changed conditons. He therefore commenced by describing somewhat fully the rocks belonging to the carboniferous formation. The mountain limestone or carboniferous limestone, which lies at the base of the system in the south of England, is a nearly pure limestone, composed almost entirely of encrinites, corals, and other similar marine forms, and attaining a thickness of two or three thousand feet. Above that lies the millstone grit, about a thousand feet thick, likewise marine, but containing the remains of land plants; overlying that are the coal measures, consisting of an alternation of beds of sandstone, slate, coal, and ironstone. In the north of England and Scotland the base of the system consists of alternating beds of limestone, sandstone, and shale, with occasional beds of coal, and above that the true coal measures. The coal was formed by the life and death of land-plants—Lepidodendron, Sigillaria, Calamites, &c., and under every bed of coal is a layer of clay—"underclay," which is nothing more nor less than the ancient soil on which the plants grew, and contains the roots of some of the above plants, *e.g.* Stigmaria, the root of Sigillaria. The remains of the plants accumulated somewhat like existing peat bogs, and were at times submerged and covered with a layer of sediment, and again upheaved and overspread by vegetation. There must have been a large continental area in the latitude in which Britain now stands to furnish the gigantic rivers at the mouths of which many of these coal-measure forests grew.

Above the carboniferous strata lie the Permian seen surrounding some of the Midland coal fields, in a strip from Derbyshire into Cumberland, and forming the base rocks of a portion of the Vale of Eden. The beds lie unconformably on or against the coal measures, implying that a vast lapse of time, sufficient to allow for the denudation of thousands of feet of thickness of strata in some places, took place between the deposition of the two formations. At the base of the Permian strata lie beds of red conglomerate, sandstone, and marl, known on the Continent as *Rothliegende;* and above those lie the magnesian limestone. In the magnesian limestone a considerable number of marine forms of life occur, but compared with the great abundance of those forms in the carboniferous limestone, the fauna seems poor and the individuals are dwarfed; out of 1800 species of shells in the carboniferous genera only 38 genera and 180 species are found in the magnesian limestone. The latter strata also contain some fossil fish in its lower beds (marl slate), of the same genera as those found in carboniferous strata, and some show considerable resemblance to those living forms inhabiting inland fresh-water areas, mentioned in the last lecture. And there are various reptiles found—Labyrinthodont reptiles—which were truly amphibious, and which in some cases have left their skeletons, but far more frequently their foot-marks impressed upon the soft mud of some ancient shore, which likewise shows occasionally rain marks and sun cracks. Some of the reptiles belong to the Protosaurian genus, closely allied to the modern crocodiles or Thecodont saurians, and therefore probably ultimately connected with the land. And a very significant point in regard to the origin of these rocks is their chemical composition, the magnesian limestone consisting of the carbonates of lime and magnesia, often in about equal proportions. Now

* Continued from p. 313.

limestone is formed from the sea-water by the agency of animals, but no creature is known which secretes carbonate of magnesia from the sea waters to make its skeleton, and therefore we may conclude that it was precipitated from chemical solutions; and this could not take place in the open sea, but must have occurred, as in the case of rock-salt in confined inland waters. It is probable that by extensive changes in physical geography, large areas of the ocean were shut off, and in the lakes thus formed, the Permian rocks were deposited, the magnesian limestone being formed by the mixture of the carbonate of magnesia, precipitated by means of evaporation with limestone built up by organic agency. Crystals of gypsum too occur in these rocks, and pseudomorphous crystals of rock-salt pointing to evaporation, and consequently concentration of these salts in the waters of confined areas. A thin pellicle of peroxide of iron surrounds the grains in the sandstone and marl, which gives the red colour to the rocks, and which peroxide was formed by the reduction of the carbonate of iron, carried into the lakes by the rivers, by means of the oxygen of the air. The lecturer had no hesitation in saying that in all those formations which we know to be truly marine the rocks are never red. So that from the paucity or absence of shells, from the remains of terrestrial or amphibious reptiles, and their foot-prints, from the occasional presence of true land plants (of the same genera, but not the same species, as in the carboniferous rocks), from the chemical composition of the rocks, from the presence of peroxide of iron, and from the presence of chemical precipitates, we are justified in concluding that the Permian rocks were deposited in great salt lakes, though perhaps not salt in every case. And a reflex of the conditions under which they were deposited may be seen in the state of the Caspian Sea (with a marine fauna like the North Sea, though the species are few and dwarfed), and of the salt lakes of Asia.

SCIENTIFIC SERIALS

THE *Lens* for November 1872, contains the following communications: "The preparation of Diatomaceæ," Christopher Johnstone, M.D.: a succinct account of the most usual and approved methods of cleaning Diatomaceous deposits. A short reply of Dr. J. J. Woodward to Dr. Lionel S. Beale; and a memorandum by Chas. Stodder, entitled "Draw-tubes *v.* Deep-eye-pieces." A continuation by Dr. J. N. Danforth of his communication on "the cell," treats of the theories of cell development. H. H. Babcock's "Flora of Chicago and its vicinity," Part IV. completes, we presume, the phanerogamic plants of Part III.; "Microscopical Memoranda for the use of Practitioners of Medicine," by Dr. J. J. Woodward, relates the results of the author's experience on "the Imbibition of the Tissues with Chloride of Gold and Osmic Acid." Prof. H. L. Smith gives a brief notice of the Bailey Collection of Diatomaceæ in the Museum of the Boston Society of Natural History. Dr. J. J. Woodward also advocates the employment of *Frussulia Saxonica* as a test of high-power definition in preference to *Amphipleura pellucida*. S. A. Briggs gives an enumeration of some of the Diatomaceæ of Upper Lake Huron and the Sault. The usual brief notes, with title-page and index, complete this number and the first volume of this American Quarterly Journal of Microscopy.

La Belgique Horticole, gives a short life of Redonté, the celebrated French painter of flowers. A description of a new tea rose, the "Pearl of Lyons," contains a short history of these plants, from which we learn that they were introduced into Europe in 1793 by an Englishman, Mr. Parsons, and reintroduced early in this century by others, Sir A. Hume being one of them. M. E. Morren describes, in a very clear and concise manner, the physiology of the nutrition of plants.

THE *Revue Bibliographique Universelle* contains short reviews of several botanical works, including that by Grisebach and Engelman, on the geographical distribution of plants, in which the world is divided into twenty-four botanical regions, several of these being, according to the reviewer, unnecessary. Referring to a work by M. Hamilton on the Botany of the Bible, the following occurs:—"Il a joint à chacun de ses articles une photographie prise sur nature, mais malheureusement dans les environs de Nice, et non point en Terre Sainte." Prof. Balfour's Introduction to the Study of Palæontological Botany is considered too deficient in detail and from the fewness of the references to other authors, the incompleteness of the Edinburgh libraries is presumed.

SOCIETIES AND ACADEMIES

LONDON

London Mathematical Society, Feb 13.—Dr. Hirst, president, in the chair. The following papers were read:—Prof. H. G. Smith, on the higher singularities of plane curves, and on systems of linear consequences.—Mr. J. Macleod, on the application of the hodograph to the solution of problems on projectiles.

Geologists' Association, February 1.—Henry Woodward, F.G.S., president, in the chair.—"On the Diprionidæ of the Moffat Shale," by Charles Lapworth, F.G.S. After reviewing the history of investigation among the biserial *Graptolites*, and the antagonistic opinions regarding their internal structure held by different palæontologists, the author stated that a careful decomposition and examination of specimen of *Chinacograptus* from the Moffat Shale, preserved in a state of relief, had forced him to the conclusion that the view of the duplicate nature of the polypary in this genus advocated by Professor Nicholson is substantially correct. The internal characters are identical with those in *Diplograptus*. The diprionidian polypary is in reality composed of two complete monoprionidian polyparies (each with its own cœnosarc, virgula, and distinct hydrotheca), placed back to back and coalescing along their flattened dorsal walls. There is certain evidence that this type of structure obtains among all, or nearly all, of the Moffat *Chinacograpti*. Nevertheless, he was not prepared to deny the accuracy of Professor Hall's interpretation of the internal characters of his *China(?)typicalis*. As long as a single doubt remained upon this point, it was argued that it would be unsafe to exclude *Retiolites* and its allies from the *Dipliotidæ*, which might meanwhile be considered as embracing three sub-families, *Diplograptidæ*, *Retiolitidæ*, and a third and intermediate sub-family, of which *C.* (?) *typicalis* is the only known example. The sub-family *Diplograptidæ* will include all those species at present referred to *Diplograptus* and *Chinacograptus*. Now that the type of structure in these two genera is proved to be identical, a new system of classification is necessary. The only remaining characters which can in all cases be employed for the purpose of separation at our command are the form of the polypary and the shape and arrangement of the hydrotheca. It was shown that the different species of the *Diplograptidæ* naturally arrange themselves into five groups, clearly individualised by striking distinctions in these characters. Each of these groups, it was contended, was of sufficient importance to be considered as forming a distinct and separate genus. In this way the genera *Climacograptus* (Hall) and *Cephalograptus* (Hopk.) would remain untouched, and the author suggested that the generic term *Diplograptus* (M'Coy) should be restricted in future to those species of which *Dip. folium* (His.) is the type, and he proposed two new genera, viz., *Orthograptus*, to include those species resembling *Dip quadrimucronatus* (Hall) and *Glyptograptus* for those formed after the pattern of *D. tamariosens* (Nich.). The second portion of the paper was devoted to a revision of the genera and species of Diplograptidæ found in the Moffat Shales, and the following new species were described:—*Orthograptus aculeatus*, *O. Carruthersi*, *O. fasilicus*, *O. Pageanus*, *O. explanatus*, *O. compactus*; *Glyptograptus gregarius*, *G. per excavatus*, *G. modestus*; *Chinacograptus styloidens*, *C. tubuliferus*, *C. Longicaudatus*, *C. Wilsoni*, *C. antiquus*, *C. brevicornis*, *C. mirabilis*.

Zoological Society, Feb. 18.—John Gould, F.R.S., V.P., in the chair.—The Secretary read a report on the additions that had been made to the Society's collection during the month of January, 1873. Amongst these were specially mentioned a pair of Fruit-Bats from Formosa, presented by the Rev. Mr. Ritchie of Takoo, and a tapir from Paraguay, which presented some points of distinction from the ordinary form of the American tapir.—Prof. Newton, F.R.S., V.P., exhibited a print by Adrian Collaert (*circa*, 1580) containing the figure of a bird, cepied in Leguat's "Voyages" (1708), and mentioned by the latter under the name of the "*Géant.*"—Extracts were read from a letter received from Dr. John Kirk, H. B. M. Consul at Zanzibar, respecting a female koodoo, and other antelopes, of which he had obtained specimens for the Society.—Mr. Garrod gave a notice of the death of a kangaroo in the Society's gardens, which had been caused by strangulation of the small intestine, produced by the folding of the elongate caecum round a loop of the small intestine.—A communication was read from Prof. G. J. Allman, F.R.S., containing a report on the *Hydroida* col-

lected during the two expeditions of H.M.S. *Porcupine* in 1869 and 1870.—Mr. W. K. Parker, F.R.S., read a memoir on Ægithognathous Birds, in which it was shown that the peculiar palatal structure of this group was met with in three stages. These might be denominated incomplete, complete, and compound Ægithognathism.—Mr. A. H. Garrod read some notes on the anatomy of the Binturong (*Arctictis binturong*) founded on the dissection of a male specimen of this animal which had recently died in the Society's Gardens.—Mr. E. L. Layard, H.B.M.Consul at Para, communicated some notes on Mr. E. W. H. Holdsworth's recently published catalogue of the birds found in Ceylon.—A communication was read from Mr. H. Adams, F.L.S., containing descriptions of eighteen new species of land and marine shells, the former from Borneo and the Island of Tobago, and the latter from Mauritius, the New Hebrides and the Persian Gulf. Mr. Adams proposed to establish a new sub-genus of *Helix*, under the name *Caldwellia*, for *H. philyrina*, Morel, and some allied species from Mauritius and the Isle of Bourbon.

Chemical Society, Feb. 20.—Dr. Frankland, F.R.S., president, in the chair. The first paper read after the usual business of the society had been transacted, was entitled "Solidification of nitrous oxide," by Mr. Wells. The gas having been previously liquefied by compression in a strong iron vessel, can be caused to solidify by the rapid evaporation of the liquid in a current of air. It somewhat resembles solid carbonic acid in appearance.—A paper on aurin, by Messrs. R. S. Dale and C. Schorlemmer, F.R.S., was then read, giving an account of the authors' investigation of the composition and chemical properties of this dye.—"Researches on the action of the copper-zinc couple on organic bodies, I. on iodide of ethyl," by J. H. Gladstone, F.R.S., and A. Tribe, was read by Dr. Gladstone; and the last communication, "On the determination of ammonia in the atmosphere," was read by the author, Mr. A. H. Smee, Jun. The method employed is to collect and examine the moisture condensed from the atmosphere, on the external surface of a suitable glass vessel filled with ice. The lecture was illustrated by carefully-made drawings of the magnified crystalline forms which are left on evaporating the liquid.

Royal Horticultural Society, Feb. 11.—Annual General Meeting.—Lord Henry G. Lennox, M.P., in the chair.—The Report of the Council stated that there were now 3,572 Fellows on the books. They thought that, notwithstanding that a portion of the Fellows preferred to have the Garden and Society kept distinct from the Exhibition, it was for the interest of the former that the two establishments should work harmoniously. They have accordingly done their best to make arrangements with Her Majesty's Commissioners for the present year. The nature of these arrangements appeared in a letter from the Commissioners appended to the Report. They excited a very stormy discussion, and the further consideration of the Report was referred to an adjourned meeting.

Feb. 12.—Scientific Committee.—Dr. Masters, F.R.S., in the chair.—A letter was read from Col. Jervoise, stating that the two plants of *Agave Americana* which had flowered during the past summer were 23 years old in 1797. The presence of the *Phylloxera vastatrix* on vines about London was stated as having been ascertained without doubt. A discussion then took place on a letter from Major-General Cotton as to the best means of arresting a belt of moving sand which threatens the destruction of Beyrout. General Meeting.—Mr. Wilson Saunders, F.R.S., in the chair.—The Rev. M. J. Berkeley commented on a fine specimen of *Vanda Cathcarti*, which, though a native of the hot valleys of Sikkim, was found to succeed best under a cool treatment. A seed-pod of *Yucca Draconis*, sent by Mr. Wilson Saunders, was noteworthy, because Yuccas rarely fruited in this country.

Feb. 18.—Adjourned Annual General Meeting.—Mr. Wilson Saunders, F.R.S., in the chair.—The consideration of the Report of the Council was resumed. A letter was read from the Commissioners reverting to the subsisting agreement between them and the Society. On the motion of Sir Alfred Slade, the Report of the Council was not adopted. The Council then intimated their intention of resigning, and the meeting again adjourned.

PHILADELPHIA

American Philosophical Society, March 15, 1872.—A paper by Prof. Daniel Kirkwood was read, entitled "On some remarkable relations between the mean motions of Jupiter, Saturn, Uranus, and Neptune."

April 15.—On the Magnetism of Rocks of the Marquette group, by Prof. F. B. Brooks, State Geologist of Michigan. Beds of this formation were shown to possess such an influence on the needle, as to be correctly located by it, even when at considerable depths.—Prof. Pliny E. Chase presented numerous new relations which he had obtained by his method of comparing molar and molecular forces. He showed that the principal maxima of the annual auroral curve follow the principal annual meteoric displays; that all the primary planets are arranged near centres of inertia, or centres of primary or secondary oscillation; that superficial gravity both at Jupiter and at the earth, acting against orbital force for a half-rotation, gives a velocity nearly equivalent to that of a planet revolving at the sun's surface; that solar gravity under the same circumstances gives the velocity of light; that the sun-spot period is governed by the centre of gyration of the planetary system; that polarity is a necessary consequence of a rotating uniformly elastic fluid; that the elasticity of hydrogen is nearly perfect, and that, therefore, its density is, approximately, 54,130,000,000 times as great as that of the luminiferous æther. He also gave several additional physical approximations to the sun's distance, all of which are within the limits of the best recent astronomical estimates.

May 3.—Prof. Rogers described a new form of galvanic battery.—Prof. Lesley described a fault in the Unaka Mountains, on the Nolichucky River in East Tennessee.—Prof. E. D. Cope made some observations on the life of the Wyandotte Cave, Indiana.

May 17.—Prof. Chase exhibited an annual auroral curve, and explained its relations to the periodic maxima and minima of meteoric displays, &c. He then presented a number of tables expressive of recent calculated planetary relationships.—Prof. Rogers explained his manner of obtaining an unlimited supply of electricity from a high-pressure steam jet, not insulated and in all weathers.—Dr. Emerson and Mr. Trego described the destruction of *Abies excelsa*, *Maclura*, and *Thuja* during the preceding winter as far south as lat. 40°.—Prof. Blodget described the meteorology of March 5, 6, and 7, during which a dry cold gale prevailed. In the succeeding spring fruit trees exhibited an inability to blossom as though paralysed.

July 19.—A paper was received from Prof. Cope "On the Tertiary Coal and Fossils of Osino Nevada." The fossils were shown to be *Planorbis* and other freshwater forms; insects (largely *Diptera*) in beautiful preservation, and fishes. The shales resemble the *papier kohle* of Bonn, and contain great numbers of leaves.—Prof. Chase read a paper on "Ætherial Oscillation, the primordial force;" and stated that certain meteorological predictions had been verified, which had been based on his observations of the rainfall at San Francisco.

August 16.—"Descriptions of some new Vertebrata from the Bridger group of the Eocene; second account of new extinct Vertebrata from the Bridger Eocene." In the former, among other new forms, was described *Mesonyx*, a genus of Carnivora or allied form with teeth with only one row of conic tubercles and with flat claws, allied to *Hyaenodon*. Also a genus allied to both Proboscidians and Rodents, without molar teeth, called *Pseudotomus*.—A communication from Prof. Cope was read on his discovery of "*Proboscidia* in the Wyoming Eocene," this order having been previously unrecognised below the Miocene in America. A new genus, *Eobasileus*, was described; dentition, i, 0; c, 1; pm, 3; m, 2, horns on the top of the head. Three species were described, *E. cornutus*, of gigantic size, represented by cranium, scapula, vertebræ, pelvis and femur complete. The horn cores trihedral, the muzzle with two horizontal superior shovel-like expansions. *E. furcatus* with bifurcate nose, with spatulate processes; and *E. pressicornis* with massive feet, flattened horns and high occiput. The tusks were dangerous weapons, a foot long, and sabre-shaped, but the molars were small.

ITALY

R. Accademia del Lincei, Jan. 5.—Prof. Respighi, in a note upon the solar diameter, proposed to show that the differences of the results in the daily observations of the duration of the meridian passage of the solar disc, ought not to be attributed to real variations in the diameter of the solar disc, caused by the temporary enlargement or diminution of the photosphere, or to variations in brightness arising from the constitution of the

photosphere, but rather to the inaccuracies of measurement which inevitably attend such very difficult observations. In observations of the contacts on the solar border by means of the micrometer, there are two principal sources of error, the influence of which may sensibly vary from day to day; they are: (1) The difference of the conditions between the contacts of the west and east limbs. Prof. Respighi observed first by a micrometer in a faintly illuminated field, and secondly in a highly illuminated one: this is apt to introduce an error variable from day to day into the observations of the same person, in proportion to the clearness or transparency of our atmosphere, and will probably become greater when the sky is less clear. (2) From the state of undulation of the solar limb, variable from day to day, there may result a sensible and variable increase of the extent of the disc or diameter of the sun. These influences will not be excluded by the proficiency of the observer, by the use of good instruments, nor by the chronographic registration of the contacts. For the purpose of more thoroughly studying these variations, and investigating their origin, recourse was recently had to the spectroscopic combination of Father Secchi, by which the solar limb or image was obtained, formed by monochromatic or almost monochromatic rays; and from a series of observations made with this apparatus it was found that the solar diameter was less by ·6″ than that given in the *Nautical Almanac*. Hence it has been inferred that by depriving the solar disc or diameter of the influence of the chromosphere its extent is diminished by about 8″ from that obtained by means of the telescope. And therefore it has been inferred that the variations in the solar diameter very probably depend on the variable increase produced on it by the chromosphere, in relation to the extent and intensity of light and the varying state of transparency of our atmosphere. Prof. Respighi, after having shown how the light of the chromosphere could not make any sensible difference to an image of the solar limb or disc, expounded the results obtained from various observations, made by him on the solar diameter by means of the spectroscopic combination alluded to, both with the objective and direct-vision prisms, applied in front of the slit of the spectroscope, using every precaution to exclude the various sources of error. From these observations it results that the duration of the passage of the solar diameter is essentially the same, taking the contacts at the various spectral lines, B, C, D, E, F, and that the measurement agrees very closely with that of the *Nautical Almanac*. The same result is obtained in determining the duration of the passage of the solar limb by means of the slit of the simple spectroscope. Hence Prof. Respighi concludes that while the difference between the solar diameter, as given by the spectroscope and that given by the telescope alone has not been proved, so the suspected origin of this difference is inadmissible, and therefore also any daily variations in the solar diameter.

Vienna

I. R. Geological Institute, Jan. 7.—Contributions to a more accurate interpretation of fossil vegetable remains from the salt-stock of Wieliczka (Galicia), by M. Dionys Stur. By dissolving in water pieces of salt from Wieliczka, which included vegetable remains, M. Stur succeeded in getting the latter in a state of preservation and purity which permitted an accurate examination; his very interesting inquiries rectify in many points the determinations made by one of the first authorities in fossil botany. Prof. Unger, who many years ago had given a description of these remains in the first volume of the memoirs of the Vienna Academy. To the most frequent of them belong pine-nuts; besides the one species, *Pinus salinarum* Partsh, described by Unger, Stur discovered two other species: *P. polonica*, which is allied to the existing *P. Massoniana* Lamb, and the larger, *P. Russeggeri*, resembling the *P. rigida* Mill. A very curious fact is noted in connection with these cones; while many of them are perfectly well preserved, many others were found with scales gnawed or bitten off, exactly in the same manner as squirrels (*Sciurus*) demolish the pine-nuts of our forests in order to get their seed corns. Pine-nuts which were not quite ripe are bitten on one side (the sun-side) only, while perfectly ripe nuts are demolished to the basis, which then shows a deceptive likeness with the cupula of an acorn. Indeed the two vegetable remains described by Unger as the cupulæ of *Quercus Saturni* and *Q. limnophila* are but pine-nuts destroyed in the same manner: moreover the oak-apples themselves, mentioned by Unger, have proved to belong to quite different plants. The so-called nut of *Q. glans Saturni* Unger, is the nut of *Carya costata* Sternb, which is also gnawed by a squirrel, whilst the nut taken by Unger for the fruit of *Q. limnophila*, is the fruit of a palm very similar to that of the existing *Raphia taedigera*, and is named by Stur *Raphia Ungeri*.—K. v. Hauer gave a description of the large quarries in the tertiary limestone of Zogelsdorf in Austria; in former years they had furnished almost all building stones for Vienna, especially for the famous tower of St. Stephen. Upon the discovery of a very good building stone nearer to the town in the Leitha mountains the quarries of Zogelsdorf decayed, but as soon as the Franz-Joseph railway, which passes very near the spot, made cheap transport practicable, they were reopened by the present possessor, Baron Suttner, and are worked now very extensively.—Dr. G. Stache described an earthquake which was felt in Vienna on January 3, some minutes before 7 o'clock in the evening. In some parts of the town, for instance in the working rooms of the Geological Institute, in the palace of Prince Liechtenstein two shocks were observed, the second tolerably vehement, with a rolling noise. The direction seemed N.W. to S.E.; the duration of the phenomenon was about four seconds.

DIARY

THURSDAY, February 27.

Royal Society, at 8.30.—On Leaf Arrangement: Dr. Hubert Airy.
Society of Antiquaries, at 8.30.—Northamptonshire Star-Chamber Proceedings, Temp. James I.: W. H. Hart.
Royal Institution, at 3.—On the Artificial Formation of Organic Substances: Prof. Rutherford.

FRIDAY, February 28.

Royal Institution, at 9.—On Livingstone's Explorations in Africa: Sir H. C. Rawlinson.
Quekett Club, at 8.
Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.

SATURDAY, March 1.

Royal Institution, at 3.—On the Philosophy of the Pure Sciences: Prof. W. K. Clifford.

MONDAY, March 3.

Entomological Society, at 7.
London Institution, at 4.—Physical Geography: Prof. Duncan.
Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.
Royal Institution, at 2.—General Monthly Meeting.
Cantor Lectures, at 8.—On the Energy of Electricity: Arthur Rigg.

TUESDAY, March 4.

Anthropological Society, at 8.—On the Looshais: Dr. A. Campbell.—Implements and Pottery from Canada: Sir Duncan Gibb, Bart, M.D.—The Ventnor Flints: Hodder M. Westropp.

HARVESTING ANTS AND TRAP-DOOR SPIDERS

Harvesting Ants and Trap-Door Spiders. Notes and Observations on their Habits and Dwellings. By J. Traherne Moggridge, F.L.S. (L. Reeve and Co., 1873.)

THIS beautifully illustrated little book is a good example of what can be done by a careful observer in a very short time. It might have been thought that the habits of European insects were pretty well known, and that a person comparatively new to the subject could not hope to add much to our knowledge. But the fact is quite otherwise, for Mr. Moggridge, in the course of a few winters spent in the south of Europe has, by careful observation, thrown considerable light on the habits and economy of two important groups of insects, and, as regards one of them, has disproved the dogmatic assertions of several eminent entomologists. Nothing is more curious than the pertinacity with which scientific men will often draw general conclusions from their own special observations, and then use these conclusions to set aside the observations of other men. Mr. Moggridge now confirms, in many of their minutest details, the accounts given by classical writers of the habits of ants. These habits were recorded with so much appearance of minute observation, that they bear the impress of accuracy; yet because the Ants of England and of Central Europe have different habits, it was concluded that the old authors invented all these details, and that they were at once accepted as truths and became embodied in the familiar sayings of the time. The ants were described as ascending the stalks of cereals and gnawing off the grains, while others below detached the seed from the chaff and carried it home; as gnawing off the radicle to prevent germination, and spreading their stores in the sun to dry after wet weather. Latreille, Huber, Kirby, Blanchard, and many less eminent authors, treat these statements with contempt, and give reasons why they cannot be true for European species, yet we here find them verified in every detail by observations at Mentone and other places on the shores of the Mediterranean. Mr. Moggridge has, however, supplemented these observations by discovering the granaries in which they are stored (sometimes excavated in solid rock), of which accurate plans are given. He has seen them in the act of collecting seeds, and has traced seeds to the granaries, from which all husks and refuse are carefully carried away; he has seen them bring out the grains to dry after rain, and nibble off the radicle from those which were germinating; lastly, he has seen them (in confinement) feed on the seeds so collected. A very curious point is, that the collections of seeds, although stored in very damp situations, very rarely germinate; yet nothing has been done to deprive them of vitality, for on being sown they grow vigorously. The species of harvesting ants observed were, *Pheidole megacephala*, *Atta structor*, *A. barbara*, and a larger and differently coloured variety of the last. *Atta structor* is found over a large part of Central Europe, yet, as it has never been observed to lay up stores of seeds in more northern countries, it either has different habits according to locality, or local observers have strangely overlooked its peculiarities. The seeds of more than thirty species of plants were found stored up, none of which were cereals; but at Hyères, M. Germain St. Pierre has observed these latter stored by ants in such quantities that he thinks their depredations must cause serious loss to cultivators. Thus we have another important confirmation of the statements of the old writers.

The second part of the book gives a very interesting and elaborate account of the curious nests of the Trap-Door spiders of the south of Europe, of which two new forms are described, one of them being constructed by a hitherto undescribed species of spider. The nests previously known have a hinged door at the upper end of the tubular nest, but Mr. Moggridge found another kind with a second door lower down, and also one with a lateral chamber the opening to which, as well as the main tube, is closed by the second door. In these nests the lower door is strong and fits closely, and can be held fast by the spider on the inside, while the upper door is for concealment only, being very thin, but almost always closely resembling the surrounding surface. In many cases it is overgrown with living moss and lichens, and Mr. Moggridge thinks that the spider plants or sows the mosses, having found little bits of moss stuck on to a newly-made door. A curious and instructive observation occurs as to the simple manner in which a protective adaptation may be brought about unconsciously. Having cut away the top of one of these nests and thus left the tube exposed on a surface of bare earth, the spider made a new door in which it stuck pieces of moss from the neighbouring moss-covered bank, thus making its nest very conspicuous by the round patch of green on a surface of fresh earth. The simple and natural habit of covering the door of the nest with any material that grows or lies around it usually leads to concealment, but the above example shows that in doing so the insect does not consciously work with this object. Even more curious is the fact that little spiders only a few days old construct nests exactly like those of the parent—tubes excavated in the earth, lined with silk and provided with one or two doors and lateral passages, as the case may be, but only about one-sixth the size. Good reasons are given for believing that these small nests are not abandoned, but enlarged from time to time as the occupant grows bigger. Whether the very young spiders build their nests independently of all teaching or experience is a curious point of inquiry to which our author adverts, and as he suggests that it might not be very difficult to rear young spiders from the egg and place them in conditions favourable for their existence, it is to be hoped that he will try the experiment and help to throw light on a subject on which we have so little positive knowledge.

The numerous coloured plates, giving full-sized representations of the spiders and their habitations, are very carefully drawn, and add greatly to the interest of one of the most original and entertaining books on natural history we have met with for some.

ALFRED R. WALLACE

SEPULCHRAL MONUMENTS OF CORNWALL

Nænia Cornubiæ. A descriptive essay, illustrative of the Sepulchres and Funereal Customs of the early Inhabitants of Cornwall. By W. Copeland Borlase, B.A., F.S.A. (London: Longmans; Truro: Netherton, 1872.)

MEETING with a recent work on any branch of the antiquities of Cornwall, by an author bearing the name of Borlase, is so much like falling in with the ancient

landmarks, after having long failed to detect them, as to be in itself a source of pleasure; and this is enhanced on learning that the author of the work before us is not only a namesake, but a great-grandson of Dr. Borlase, the author of "Observations on the Antiquities, Historical and Monumental, of the County of Cornwall," published at Oxford in 1753.

Whilst we have read the book with much pleasure, we have now and then had to regret a lack of distinct method, a tendency to digress, and a tone somewhat too judicial when dealing with questions on which the author differs from older and more experienced antiquaries. As we learn from the Dedication that the author is young, we have little or no doubt that such blemishes will be less conspicuous in the "second series" he contemplates, and which we hope to see at no distant period.

He declines to accept "the hypothetical distinctions drawn between stone, bronze, and iron periods," on account of a few facts he has met with, but which do not appear to contain any danger to the distinctions in question. He lays down the excellent law that the antiquary "should never be ready to sacrifice a fact merely because it is hard to explain, upon the altar of a much more indefensible theory," and soon after reminds us of the well-known maxim—"Do as I say, not as I do;" for when mentioning two instances of graves in each of which, he says, "the monument has consisted of two pillars of unhewn granite, placed at no great distance apart," he adds that "Graves adorned in this manner are the common property of all ages and all religions," and then slides into an attempt to make Homer support the converse proposition—that such pillars are to be always regarded as indications of a grave. For this purpose he quotes the *Iliad*, xxxiii. 329, and gives the following as Mr. Wright's translation:—

> "On either side
> Rise two white stones, set there
> To mark the tomb of some one long since dead."

We are afraid that Mr. Borlase has here been willing to sacrifice a *fact* rather than his *theory*. The passage in Homer and its bearing on the question had been previously mentioned by Sir John Lubbock,* who also uses Wright's translation. At the burial of Patroclus, Nestor, pointing out to his son the course for the chariot race, says:—

> "Plain is the goal
> That now I tell thee of; nor canst thou miss it—
> Upraised four cubits high above the ground
> There stands a wizen stump, of oak or pine,
> Not rotted by the rain. On either side—
> Where narrowest is the way, and all the course
> Around is smooth—rise two white stones, set there
> To mark the tomb of some one long since dead,
> Or form the goal for men in ages past,
> But now the goal of Peleus' god-like son."

It is obvious, from the last line but one, that Homer was by no means certain that such stones invariably marked a grave.

Having pointed out the few defects of the book which struck us, we now proceed to the more agreeable duty of giving a brief summary of its contents.

Mr. Borlase rejects unconditionally the hypothesis that the megalithic remains in Cornwall are druidical. To Sir J. Lubbock's remark that "A complete burial place may be described as a dolmen, covered by a tumulus, and surrounded by a stone circle; often, however, we have only the tumulus, sometimes only the dolmen, and sometimes only the circle," he proposes to add, "sometimes only two adjacent menhirs, and sometimes only the single standing stone," and states that "under the one or the other head may be classed every mode of interment hitherto discovered in Cornwall."

He divides European Cromlechs into three classes: 1. The Dolmen, or "table-stone" proper, where the vertical supports do not *enclose* a space, or form a continuous wall. 2. The Larger Kist-Vaen, or stone chest, where the vertical supports and the covering stone form an enclosed chamber, designed to hold the body, and covered, sometimes very slightly, with a mound. 3. Monuments similar in structure to the Kist-Vaen just described; but instead of receiving the body are merely cenotaphs raised over the actual grave. There is in Cornwall no instance of the third class.

The first, or dolmen, is much higher than the others, and is comparatively rare, there being but two examples in the county. Lanyon Cromlech, in the parish of Madron, near Penzance, consists entirely of granite, and was described by Dr. Borlase. It fell in 1815, and was set up again in 1824, but some of the stones had been broken. The covering stone, or quoit as it is termed in Cornwall, measured 47 ft. in circumference, and averaged 20 in. in thickness. It was supported by three thin unhewn pillars, at a height sufficient to permit a man on horseback to sit under it. Caerwynen Cromlech, near Camborne, resembles that just described in construction and material. The quoit measures 12·75 ft., and its three supporters varied from 5·17 ft. to 4·9 ft. high. This monument has also fallen and been replaced. A simple, but unoccupied, grave cut in the soil was found under the quoit at Lanyon, but it does not appear that any search has been made at Caerwynen.

Of the second class of cromlechs, or larger kist-vaens, Mr. Borlase describes no fewer than eight examples—five near the western extremity, two near the centre of the northern coast, and one in the south-east of the county; but no more than one in each division is now perfect or approximately so. They all consist of the rock of the district or its vicinity, and six of them are of granite, whilst two are of a "sparry rock." One is in a valley, but at least five occupy conspicuous positions on high ground. There are distinct indications that several of them were covered with a barrow of earth or stones, and one, Lower Lanyon Cromlech, was so covered when it was found. The author claims for the Chywoone or Chûn Cromlech, in the parish of Morvah, near Penzance, the distinction of being the most perfect and compact now in the county, and ventures on the following speculation respecting the process of its erection:—The east and west ends, each 6·3 ft. high and 3·9 ft. and 4 ft. broad respectively, were first set up 6 ft. apart. Against their western edges a flat block of granite, 8·3 ft. long, was placed in a slanting position. On this northern side, probably over this sloping stone, with the assistance of an embankment and rollers, a rough slab of hard-grained granite, convex on one side, 12 ft. in length and breadth, and from 14 in. to 2 ft. in thickness, was raised as the covering-stone.

* "Prehistoric Times," 2nd edition, 1869, pp. 109, 110.

Finally a stone 7·67 ft. long, but not high enough to reach the covering stone, was placed on the south side. The chamber is 7 ft. high within, and a small pit seems to have been sunk in the natural soil at the centre. The pile is surrounded, and was probably covered, with a barrow, which still in some places nearly reaches the top of the side stones. It measures 32 ft. in diameter and is surrounded with upright stones. The interstices between the sides of the chamber were filled with small stones, calculated to prevent the entrance of any rubbish.

The Pawton Cromlech, in the parish of St. Breock, near Wadebridge, occupies high ground, and is intact. The kist, 7·5 ft. long, 2 ft. wide at one end and 3·5 ft. at the other, and at least 5 ft. deep, is formed with eight sparry side-stones, more than half buried in an oval tumulus, 60 ft. long. The quoit, also a sparry stone, supported by only three of the side-stones, is 7 ft. broad, 2·5 ft. thick, and, though a portion of it has been broken off, still 13 ft. long.

Trethevy, or Trevethy, Cromlech, or "Stone," in the parish of St. Cleer, near Liskeard, in south-east Cornwall, is stated by the author to be the largest, though perhaps the least known of the Cornish cromlechs. Nevertheless, he adds that it was described by Norden about 1610, and has been the subject of two papers in the present century. It consists of six upright stones, only three of which support a quoit, 13 ft. long, 9 broad, and 1 thick, which, on account of the unequal heights of its supporters, is 13 ft. above the ground at one point, and not more than 7·5 feet at another. The eastern or principal and highest supporter, rising nearly 10 ft. above the small mound on which the whole stands, has almost the appearance of a wrought stone. A ruder stone, almost equally high, rests against it like a buttress. The two stones on each side of the chamber are several feet shorter. The western end is open, but an eighth stone, considerably longer than the side-stones, lying lengthways along the kist, as if it had fallen there, was probably the supporter of that extremity. The interior of the chamber is from 9 to 10 ft. long, and from 5·5 to 6·5 ft. broad. There is near the bottom of the eastern supporter an aperture 2 ft. high, and 1·75 broad, and in the north-east corner of the quoit, where it extends beyond the kist, a hole not quite circular, from 6 to 8 in. across. Norden speaks of the latter as "an arteficiall holl, which served as it seemeth to put out a staffe, whereof the house itself was not capable." Mr. Pattison, a careful student of the geology and antiquities of Cornwall, also states that "the sides are smooth, as if worn by a staff;" and Mr. Borlase is of opinion that "such is, without doubt, the account of it." If this be so, it apparently indicates that the cromlech, whatever its origin, had not been restricted to funeral uses. The author calls attention to the fact that a hole is frequently found in the dolmens of Eastern Europe and India, adding, however, that this always occurs in one of the sides and communicates with the interior of the chamber, whilst in the Cornish example it passes through an overlapping portion of the quoit. Without expressing an opinion on this question, we would remind those who have "done" Dartmoor that they have probably been taken by the guide to see, lying in some of the streams, blocks of granite having approximately circular smooth holes passing completely through them, and, though there could be no doubt that they were due to the action of running or falling water, have been expected to regard them as somewhat mysterious. Is it not possible that, when choosing their slabs, one which happened to be thus naturally perforated, if suitable in all other respects, would be selected rather than rejected by the cromlech builders? Trethevy Cromlech consists of granite, and Mr. Pattison, quoted by Mr. Borlase, has called attention to the fact that this rock, where nearest the cromlech, occurs as boulders about half a mile distant across a broad upland valley, and adds that "the builders must therefore have credit for the exertion of combined strength and skill in transporting these enormous masses of rock across the hollow and up the hill on which they stand." Though, if necessary, we are quite prepared to concur in this, it must not be forgotten that the agency which lodged boulders on one side of the valley, may perhaps have deposited a few on the other, so that the builders may have found their materials nearer home.

Zennor Cromlech, in the parish of the same name, near St. Ives, now dismantled, was in the time of Dr. Borlase the most interesting and perfect kist-vaen in West Cornwall, and remarkable on account of the extension of the side-stones beyond the eastern end of the chamber, where with the aid of two additional stones, they formed a little cell. Such an addition appears to be unique in Cornwall, but in Wales and Anglesea it seems to be the rule rather than the exception for a small kist-vaen to exist side by side with the large one.

Though there are no *Passage graves* in Cornwall in the sense in which the term is used by Swedish antiquaries, there are several instances of long chambers buried in tumuli, and roofed with large flat stones, and, as in Denmark, termed "Giant's Graves." In 1756 Dr. Borlase described the largest of a group in the island of St. Mary, in Scilly, as 4·5 ft. wide at the mouth, 13·6 ft. long, and 3·6 ft. high, covered from end to end with large flat stones, and having a tumulus of rubbish on top of all.

The largest of a group of three in the parish of Zennor was described and figured in the *Gentleman's Magazine*, July 1865, by Mr. J. T. Blight, who stated that its direction was from N.W. to S.E., and that its dimensions were 9·5 ft. long, 4 ft. wide, and 4·3 ft. high. The roofing slabs, like those in St. Mary's, were of granite; the first, being 6 in. lower than the others, appeared to be designed as a lintel, and made the clear height beneath it no more than 3·5 ft.. The walls were of neat masonry, similar to the hedging work still in use in the neighbourhood; and the whole was covered with a tumulus 70 ft. in circumference, 8 ft. high, and built round at its base with large stones.

Near the village of Castle Euny, in the parish of Sancreed, near Penzance, Mr. Borlase discovered a chambered tumulus in April 1863, in a valley long known to be rich in ancient remains. The tumulus is conical, 8 ft. high and 50 ft. in circumference, and supported at the base with large granite stones, one rising 4 ft. above the ground. The Chamber is 6 ft. long, 3 ft. broad at the entrance and 3·75 at the opposite or northern end, and 3·5 ft. high. Each side and end consists of a single block of granite resting on an artificial elevation 2 ft. high, and the roof is formed of two stones. Though probably

the most perfect barrow of its kind in the west of England, it was used by the farmer as a shelter for sheep or pigs, but it is not known when it was opened.

(*To be continued.*)

OUR BOOK SHELF

The Useful Plants of India, with Notices of their chief Value in Commerce, Medicine, and the Arts. By Col. Heber Drury. Third edition, with Additions and Corrections. (W. H. Allen and Co., 1873.)

THE first edition of this useful work was published in 1858, since which period our knowledge of the economical products of our vast Indian possessions has greatly increased; and we have here an enumeration of 600 herbs or trees from which more or less valuable substances are obtained. The species are aranged in alphabetical order, the natural order and native and English names of each are given, followed by a description, and an account of its economic uses, taken from various standard works, or from the author's own observation. The list is not confined to natives of the country, but includes also such introduced plants as are largely cultivated and of great economic importance, as cinchona, tea, cacao, tobacco, and the Australian eucalyptus, now so extensively planted to replace the forests which have been destroyed in many parts of the peninsula to the great deterioration of the climate. In an appendix are statistics of the cultivation of cinchona, indigo, tea, and some of the fragrant woods, a table of exports and their value, and lists of synonyms in the Hindostanee, Bengalee, Tamil, Teloogoo, and Malayalam languages. The technical descriptions, and other details, have been worked out with great care, and with abundant reference to original authorities, as far as was possible to any one undertaking a work of this description at Trevandrum, and without access to the libraries and herbaria which are at the command of students in this country. Col. Drury has, however, obtained the assistance of Dr. Hugh Cleghorn, and other practical botanists, and his work is one that can be fully relied on as giving an accurate and nearly exhaustive account of the economical productions of our Indian empire.

A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

External Perception in Horses

MAY I be allowed to express my entire agreement with the theory about smell in dogs, brought forward by Mr. Wallace and Mr. Croom Robertson. The latter gentleman's arguments, in your last number, seem to me as sound in fact as they are metaphysically acute.

May I assure him, from long observation, that horses and donkeys "think with their noses" as certainly, though not, I believe, as acutely or as continuously as dogs do. But the eye-memory of a horse seems to me so much more exercised than his nose-memory, that he is, perhaps more able, when lost, to find his way home than is the dog, who has smelt everything, but looked at very little.

C. KINGSLEY

Feb. 28

External Perception in Dogs

MR. G. CROOM ROBERTSON'S and Mr. Alfred W. Bennett's observations may be easily tested by the cases of blind dogs. A blind dog in my house finds her way about as truly as a sighted dog, so that a stranger on seeing her would not be aware of her blindness. As she lost her sight by illness, she has of course the precedent knowledge derived from seeing.

To a considerable extent this case answers Mr. Bennett's requirements.

HYDE CLARKE

St. George's Square, March 1

Mr. Wallace on Instinct

IN reference to the letters of Mr. Darwin and Mr. Wallace, the following passage from Boswell's Life of Johnson may be worth recalling:—

"The custom of eating dogs at Otaheite being mentioned, Goldsmith observed that this was also a custom in China; that a dog-butcher there is as common as any other butcher; and that when he walks abroad, all the dogs fall on him. Johnson.—'That is not owing to his killing dogs, sir. I remember a butcher at Lichfield, whom a dog, that was in the house where I lived, always attacked. It is the smell of carnage which provokes this, let the animals he has killed be what they may.' Goldsmith.—'Yes; there is a general abhorrence in animals at the signs of massacre. If you put a tub full of blood into a stable, the horses are like to go mad.'" (Croker's Ed., vol. iii. p. 275.)

Effect of Light on the Electric Conductivity of Selenium

IT is of course impossible not to feel intense interest in the statement (NATURE, vol. vii. p. 303) which Mr. Willoughby Smith makes and which Mr. Latimer Clark endorses. That I have been unable to obtain the same result has doubtless been due to my having worked under conditions different from those existing in Mr. Smith's experiments. My failure has not been one of degree, but has been absolute. I have not only been unable to find that light increases the electric conductivity of selenium, but I have failed to get a current through selenium at all, even through a thickness of 0·1 millimetre. As I do not know how to put myself at once in direct communication with Mr. Smith, perhaps you will permit me to ask him through your columns to guide me on the following points:—

(*a.*) What was the form of battery employed, and what its power of overcoming British Association units of resistance?

(*b.*) What was the molecular condition of the "metal" (*sic*) employed,—*vitreous* or *crystalline*?

(*c.*) Where can "bars" of selenium be obtained which will afford the results stated?

(*d.*) Are there any unstated conditions essential to the successful production of the phenomenon?

HARRY NAPIER DRAPER

IN the description given in NATURE of February 20 last, of the very remarkable variations in the electrical resistance of bars of selenium due to the action of light, no detail is given to show how such an excessively high resistance as 1400 megohms is measured.

I am anxious to repeat the investigation of this very interesting, and as far as I know, wholly unexpected property of selenium, my idea being to measure the resistance of the bars when exposed to the light of the solar spectrum, noting the position in which the effect is at a maximum, and the extent to which the resistance is affected in the different parts of the spectrum.

But before I can do this I must be able to measure these enormously high resistances satisfactorily, and I would therefore ask if you or any of your readers would tell me how I am to do this, using resistance coils up to 60,000 B.A.U., and a reflecting galvanometer with a resistance of 1,200 B.A.U.

The Zodiacal Light

SINCE I last wrote upon this subject my views have been strongly confirmed. Both branches of the zodiacal light have been visible for some time past, and it is either getting brighter, or four months' continual practice enables me to detect its presence under unfavourable circumstances much more readily.

The night of January 30 was wonderfully fine; the ground of the heavens was intensely black, and the Milky Way was simply one blaze of light from the zenith to the very horizon: only on such nights as these are observations of the zodiacal light worth recording; all others must be very imperfect.

That night the western branch was very distinct from the horizon up to the Hyades in Taurus; at this point its breadth was much greater than on November 27 ult.; here it probably crossed first the branch of the Milky Way which tends towards Orion, then the Milky Way itself, and so was not visible for about 40° on the Ecliptic; but it became visible again in Gemini, though very faint, and it did not quite reach Præsepe in Cancer.

The eastern branch was fainter than the western, and at midnight it was seen from γ Virginis, near the horizon, up to Præsepe in the zenith, as a broad and tapering cone of light.

Hence the zodiacal light, when seen in perfection, consists of two cones of light, whose common axis is the Ecliptic, and whose common vertex is a point on that axis almost exactly 180° from the sun. The fact that the western branch is brighter than the eastern also confirms my idea of its origin, the brighter branch being over the warmer portion of the earth's surface; but I hope to make more observations of its breadth at different times of the year before writing more on this subject.

Jamaica, Feb. 6 MAXWELL HALL

[We hope our correspondent will continue to send us more of his interesting and valuable letters. It is indeed a great gain to science to have an observer stationed on the vantage ground which he occupies.—ED.]

As no one has replied to Maxwell Hall's letter on the zodiacal light (vol. vii. p. 203), I might state that his theory that the earth has two tails which stretch to an indefinite distance away from the sun is not in accordance with observation, for I have often seen the zodiacal light 180° off the sun. This is no proof against M. H.'s other idea that the two tails curve round and meet; but is there anything in M. H.'s observations contrary to the generally received theory of the zodiacal light? This is that it is not a ring, but a somewhat lens-shaped disc of light, brightest and thickest at its centre (at the sun), and gradually growing thinner and less dense, till it seems to vanish some distance beyond the earth's orbit. Its thickness at its centre would therefore be 60,000,000 miles, or more, according to M. H.'s observation. The circumstance that he could not see it more than 177° off the sun might very likely be accounted for by the milky way obscuring it there. T. W. BACKHOUSE

West Hendon House, Sunderland, Feb. 10

The Meteoric Shower

THE shower of meteors on the night of Nov. 27 last year was evidently well seen in Europe, as I had anticipated, but no notice seems to have been taken of the shower on the night of the 24th. On that night there was an equally fine display in Jamaica, from about the same radiant point; the night of the 25th was cloudy, and only a few meteors were seen on the night of the 26th, which was clear; and the shower on the 27th was simply a repetition of the shower on the 24th; but on both occasions the numbers seen here were somewhat less than in Europe.

These meteors must therefore form two almost distinct bands passing round the sun, which their association with the comet of Biela renders particularly interesting; it is just possible that these two bands intersect, and that one part of the comet belongs to one band and the other part to the other, and that they came into notice and actual contact about the same time in the year 1846, and of course afterwards separated.

Jamaica, Jan. 5 MAXWELL HALL

Maupertius on the Survival of the Fittest

CONSIDERING that the theories of Darwin and Spencer are among the most important additions ever made to human knowledge, it seems to be a matter of much interest to trace out any occasional glimpses which previous philosophers may have had of the Principles of Natural Selection. In a long note appended by Lord Bolingbroke to his fourth essay concerning Authority in matters of Religion (octavo edition of the Philosophical Works, 1754, vol. ii. p. 253; quarto edition, 1754, vol. iv. p. 255), he reviews a Memoir by Maupertius printed in the History of the Royal Academy of Berlin, for the year 1746. Speaking of the appearances of design, Lord Bolingbroke says:—"Mr. Maupertius proceeds, and admits, but admits, as it were, for argument's sake alone, that the proportion of the different parts and organs of animals to their wants carries a more solid appearance; and he judges that they reason very ill who assert that the uses to which these parts and organs are applied, were not the final causes of them, but that they are so applied because the animal is so made. Chance gave eyes and ears; and since we have them we make use of them to see and hear. He thinks, however, it may be said, that chance having produced an immense number of individuals, those of them whose parts and organs were proportioned to their wants, have subsisted, whilst those who wanted this proportion have perished and disappeared. Those who had no mouth, for instance, could not eat and live; those who wanted the organs of generation could not perpetuate their species; and thus from the present state of things theists draw an argument which will appear fallacious when it is applied to the possible original of things."

I am not aware that notice has been drawn to this distinct allusion to the survival of the fittest. So far as regards the introduction of the notion of *chance* the statement is no doubt erroneous. W. STANLEY JEVONS

Manchester, Feb. 12

"Diathermanous" or "Transfervent"

THE words "transfervent" and "transfervency" are similar in form to "transparent" and "transparency," and clearly convey their meaning to those who cannot trace them to their source. In number of syllables, also, and in sound are they not more English, or as a Greek might say, less barbarian than words of five, six, or seven syllables which are coined directly from the Greek, but which do not suit so well the Saxon tongue?

W. G. ADAMS

Flight of Projectiles—A Query

I SHALL feel thankful to any of your numerous mathematical correspondents who will kindly favour me with a simple formula for determining the deflection in the flight of a leaden cylindro-conoidal projectile—the time of flight of which is known—caused by wind of known force acting at different angles to the vertical plane of the trajectory, with an application of the formula to the following cases. Any other cause of deviation, such as that due to rotation, &c., may be neglected:—

Suppose the bullet to be 1·27″ long, and its diameter ·447″, weight 480 grs. and the wind to be of force 4, approximate pressure 4 lbs. per square inch, what is the deviation?

1. When the wind acts at right angles to the trajectory?
2. When it acts at any angle less than a right angle, say 45°?

ON ACTION AT A DISTANCE*

WE have now arrived at the great discovery by Örsted of the connection between electricity and magnetism Örsted found that an electric current acts on a magnetic pole, but that it neither attracts it nor repels it, but causes it to move round the current. He expressed this by saying that "the electric conflict acts in a revolving manner."

The most obvious deduction from this new fact was that the action of the current on the magnet is not a push-and-pull force, but a rotatory force, and accordingly many minds were set a-speculating on vortices and streams of æther whirling round the current.

But Ampère, by a combination of mathematical skill with experimental ingenuity, first proved that two electric currents act on one another, and then analysed this action into the resultant of a system of push-and-pull forces between the elementary parts of these currents.

The formula of Ampère, however, is of extreme complexity, as compared with Newton's law of gravitation, and many attempts have been made to resolve it into something of greater apparent simplicity.

I have no wish to lead you into a discussion of any of these attempts to improve a mathematical formula. Let us turn to the independent method of investigation employed by Faraday in those researches in electricity and magnetism which have made this institution one of the most venerable shrines of science.

No man ever more conscientiously and systematically laboured to improve all his powers of mind than did Faraday from the very beginning of his scientific career.

* Continued from p. 325.

But whereas the general course of scientific method then consisted in the application of the ideas of mathematics and astronomy to each new investigation in turn, Faraday seems to have had no opportunity of acquiring a technical knowledge of mathematics, and his knowledge of astronomy was mainly derived from books.

Hence, though he had a profound respect for the great discovery of Newton, he regarded the attraction of gravitation as a sort of sacred mystery, which, as he was not an astronomer, he had no right to gainsay or to doubt, his duty being to believe it in the exact form in which it was delivered to him. Such a dead faith was not likely to lead him to explain new phenomena by means of direct attractions.

Besides this, the treatises of Poisson and Ampère are of so technical a form, that to derive any assistance from them the student must have been thoroughly trained in mathematics, and it is very doubtful if such a training can be begun with advantage in mature years.

Thus Faraday, with his penetrating intellect, his devotion to science, and his opportunities for experiment, was debarred from following the course of thought which had led to the achievements of the French philosophers, and was obliged to explain the phenomena to himself by means of a symbolism which he could understand, instead of adopting what had hitherto been the only tongue of the learned.

This new symbolism consisted of those lines of force extending themselves in every direction from electrified and magnetic bodies, which Faraday in his mind's eye saw as distinctly as the solid bodies from which they emanated.

The idea of lines of force and their exhibition by means of iron filings was nothing new. They had been observed repeatedly and investigated mathematically as an interesting curiosity of science. But let us hear Faraday himself, as he introduces to his reader the method which in his hands became so powerful.*

"It would be a voluntary and unnecessary abandonment of most valuable aid if an experimentalist, who chooses to consider magnetic power as represented by lines of magnetic force, were to deny himself the use of iron filings. By their employment he may make many conditions of the power, even in complicated cases, visible to the eye at once, may trace the varying direction of the lines of force and determine the relative polarity, may observe in which direction the power is increasing or diminishing, and in complex systems may determine the neutral points, or places where there is neither polarity nor power, even when they occur in the midst of powerful magnets. By their use probable results may be seen at once and many a valuable suggestion gained for future leading experiments."

Experiment on Lines of Force

In this experiment each filing becomes a little magnet. The poles of opposite names belonging to different filings attract each other and stick together, and more filings attach themselves to the exposed poles, that is, to the ends of the row of filings. In this way the filings, instead of forming a confused system of dots over the paper, draw together, filing to filing, till long fibres of filings are formed, which indicate by their direction the lines of force in every part of the field.

The mathematicians saw in this experiment nothing but a method of exhibiting at one view the direction in different places of the resultant of two forces, one directed to each pole of the magnet; a somewhat complicated result of the simple law of force.

But Faraday, by a series of steps as remarkable for their geometrical definiteness as for their speculative ingenuity, imparted to his conception of these lines of force a clearness and precision far in advance of that with which the mathematicians could then invest their own formulæ.

* Exp. Res. 3284.

In the first place Faraday's lines of force are not to be considered merely as individuals, but as forming a system, drawn in space in a definite manner, so that the number of the lines which pass through an area, say of one square inch, indicates the intensity of the force acting through that area. Thus the lines of force become definite in number. The strength of a magnetic pole is measured by the number of lines which proceed from it; the electrotonic state of a circuit is measured by the number of lines which pass through it.

In the second place each individual line has a continuous existence in space and time. When a piece of steel becomes a magnet, or when an electric current begins to flow, the lines of force do not start into existence each in its own place, but as the strength increases new lines are developed within the magnet or current, and gradually grow outwards, so that the whole system expands from within, like Newton's rings in our former experiment. Thus every line of force preserves its identity during the whole course of its existence, though its shape and size may be altered to any extent.

I have no time to describe the methods by which every question relating to the forces acting on magnets or on currents, or to the induction of currents in conducting circuits, may be solved by the consideration of Faraday's lines of force. In this place they can never be forgotten. By means of this new symbolism, Faraday laid down with mathematical precision the whole theory of electro-magnetism, in language free from mathematical technicalities, and applicable to the most complicated as well as the simplest cases. But Faraday did not stop here. He went on from the conception of geometrical lines of force to that of physical lines of force. He observed that the motion which the magnetic or electric force tends to produce is invariably such as to shorten the lines of force and to allow them to spread out laterally from each other. He thus perceived in the medium a state of stress, consisting of a tension like that of a rope, in the direction of the lines of force, combined with a pressure in directions at right angles to them.

This is quite a new conception of action at a distance, reducing it to a phenomenon of the same kind as that action at a distance which is exerted by means of the tension of ropes and the pressure of rods. When the muscles of our bodies are excited by that stimulus which we are able in some unknown way to apply to them, the fibres tend to shorten themselves and at the same time to expand laterally. A state of stress is produced in the muscle, and the limb moves. This explanation of muscular action is by no means complete. It gives no account of the cause of the excitement of the state of stress, nor does it even investigate those forces of cohesion which enable the muscles to support this stress. Nevertheless, the simple fact, that it substitutes a kind of action which extends continuously along a material substance for one of which we know only a cause and an effect at a distance from each other, induces us to accept it as a real addition to our knowledge of animal mechanics.

For similar reasons we regard Faraday's conception of a state of stress in the electro-magnetic field as a possible method of explaining action at a distance by means of the continuous transmission of force, even though we do not know how the state of stress is produced.

But one of Faraday's most pregnant discoveries, that of the magnetic rotation of polarised light, enables us to proceed a step further. It has been pointed out by Sir W. Thomson that the phenomenon, when analysed into its simplest elements, can be expressed thus: that of two circularly polarised rays of light, precisely similar in configuration, but rotating in opposite directions, that ray is propagated with the greater velocity which rotates in the

same direction as the electricity of the magnetising current.

It follows from this, by strict dynamical reasoning, that the medium under the action of magnetic force must be in a state of rotation—that is to say, that small portions of the medium, which we may call molecular vortices, are rotating, each on its own axis, the direction of this axis being that of the magnetic force.

Here, then, we have an explanation of the tendency of the lines of magnetic force to spread out laterally and to shorten themselves. It arises from the centrifugal force of the molecular vortices. The mode in which electromotive force acts in starting and stopping the vortices is more abstruse, though it is of course consistent with dynamical principles.

We have thus found that there are several different kinds of work to be done by the electro-magnetic medium if it exists. We have also seen that magnetism has an intimate relation to light, and we know that there is a theory of light which supposes it to consist of the vibrations of a medium. How is this luminiferous medium related to our electro-magnetic medium?

It fortunately happens that electro-magnetic measurements have been made from which we can calculate by dynamical principles the velocity of propagation of small magnetic disturbances in the supposed electro-magnetic medium.

This velocity is very great, from 288 to 314 millions of metres per second, according to different experiments. Now the velocity of light, according to Foucault's experiments, is 298 millions of metres per second. In fact, the different determinations of either velocity differ from each other more than the estimated velocity of light does from the estimated velocity of propagation of small electromagnetic disturbance. But if the luminiferous and the electro-magnetic media occupy the same place, and transmit disturbances with the same velocity, what reason have we to distinguish the one from the other? By considering them as the same, we avoid at least the reproach of filling space twice over with different kinds of æther.

Besides this, the only kind of electro-magnetic disturbance which can be propagated through a non-conducting medium is a disturbance transverse to the direction of propagation, agreeing in this respect with what we know of that disturbance which we call light. Hence, for all we know, light also may be an electro-magnetic disturbance in a non-conducting medium. If we admit this, the electro-magnetic theory of light will agree in every respect with the undulatory theory, and the work of Thomas Young and Fresnel will be established on a firmer basis than ever, when joined with that of Cavendish and Coulomb by the keystone of the combined sciences of light and electricity—Faraday's great discovery of the electromagnetic rotation of light.

The vast interplanetary and interstellar regions will no longer be regarded as waste places in the universe, which the Creator has not seen fit to fill with the symbols of the manifold order of His kingdom. We shall find them to be already full of this wonderful medium; so full, that no human power can remove it from the smallest portion of space, or produce the slightest flaw in its infinite continuity. It extends unbroken from star to star, and when a molecule of hydrogen vibrates in the dogstar, the medium receives the impulses of these vibrations; and after carrying them in its immense bosom for three years, delivers them in due course, regular order, and full tale into the spectroscope of Mr. Huggins, at Tulse Hill.

But the medium has other functions and operations besides bearing light from man to man, and from world to world, and giving evidence of the absolute unity of the metric system of the universe. Its minute parts may have rotatory as well as vibratory motions, and the axes of rotation form those lines of magnetic force which extend in unbroken continuity into regions which no eye has seen, and which by their action on our magnets, are telling us in language not yet interpreted what is going on in the hidden under-world from minute to minute and from century to century.

And these lines must not be regarded as mere mathematical abstractions. They are the directions in which the medium is exerting a tension like that of a rope, or rather like that of our own muscles. The tension of the medium in the direction of the earth's magnetic force is in this country one grain weight on eight square feet. In some of Dr. Joule's experiments, the medium has exerted a tension of 200 lbs. weight per square inch.

But the medium, in virtue of the very same elasticity by which it is able to transmit the undulations of light, is also able to act as a spring. When properly wound up, it exerts a tension, different from the magnetic tension, by which it draws oppositely electrified bodies together, produces effects through the length of telegraph wires, and when of sufficient intensity, leads to the rupture and explosion called lightning.

These are some of the already discovered properties of that which has often been called vacuum, or nothing at all. They enable us to resolve several kinds of action at a distance into actions between contiguous parts of a continuous substance. Whether this resolution is of the nature of explication or complication, I must leave to the metaphysicians.

ON LEAF-ARRANGEMENT*

ASSUMING, as generally known, the main facts of Leaf-arrangement—the division into the whorled and spiral types, and in the latter more especially the establishment of the convergent series of fractions, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{3}{8}$, $\frac{5}{13}$, $\frac{8}{21}$, $\frac{13}{34}$, $\frac{21}{55}$, $\frac{34}{89}$, $\frac{55}{144}$, &c., as representatives of a corresponding series of spiral leaf-orders among plants—we have to ask what is the meaning that lies hidden in this law?

Mr. Darwin has taught us to regard the different species of plants as descended from some common ancestor; and therefore we must suppose that the different leaf-orders now existing have been derived by different degrees of modification from some common ancestral leaf-order.

One spiral order may be made to pass into another by a twist of the axis that carries the leaves. This fact indicates the way in which all the spiral orders may have been derived from one original order, namely, by means of different degrees of twist in the axis.

We naturally look to the simplest of existing leaf-orders, the two ranked alternate order $\frac{1}{2}$, as standing nearest to the original; for it is manifest that the orders at the other extreme of the series, the condensed arrangement of scales on fir-cones, of florets in heads of *Compositæ*, of leaves in close-lying plantains, &c., are special and highly developed instances, to meet special needs of protection and congregation: they are, without doubt, the latest feat of phyllotactic development; and we may be sure that the course of change has been from the simple to the complex, not the reverse. This point will be illustrated by experiment below.

But first, what are the uses of these orders?—and at what period of the leaf's life does the advantage of leaf-order operate? The period must be that at which the leaf-order is most perfect; not therefore when the twig is mature, with long internodes between the leaves; but while the twig and its leaves are yet *in the bud;* for it is in the bud (and similar crowded forms) that the leaf-order is in perfection, undisturbed by contortions or inequalities of growth; but, as the bud develops into the twig, the leaves become separated, the stem often gets a twist, the leaf-stalks are curved and wrung to present the blades

* Abstract of paper read by Mr. Hubert Airy, M.A., M.D., before the Royal Society, February 27, 1873.

favourably to the light, and thus the leaf-order that was perfect in the bud is disguised in the grown twig.

In lateral shoots of yew and box and silver fir we see how leaves will get their stalks twisted to obtain more favourable exposure to light; and if general distribution round the stem were useful to the adult leaves, we should expect the leaves of a vertical elm-shoot (for example) to secure such distribution by various twists of stalk and stem; but the leaf-blades of the elm keep their two ranks with very great regularity. This goes to show that it is not in the mature twig that the leaf-order is specially advantageous.

In the bud, we see at once what must be the use of leaf-order. It is for the economy of space, whereby the bud is enabled to retire into itself and present the least surface to outward danger and vicissitudes of temperature. The fact that the order $\frac{1}{2}$ does not exhibit this advantage in any marked degree, supports the idea that this order is the original from which all the more complex spiral orders have been derived.

The long duration of the bud-life, as compared with the open-air life of the leaf, gives importance to the conditions of the former. The open-air life of the bud is twelve months, and adding the embryo-life of the bud, we have about a year and a half for the whole life of the bud; and for the twelve months of its open-air life it is in a state of siege, against which a compact arrangement of its embryo-leaves within must be of great value. But the open-air life of the unfolded leaves is (except in evergreens) not more than six months.

That the order $\frac{1}{2}$ would under different degrees of contraction (with twist) assume successively the various spiral orders that exist in nature, in the order of their complexity, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{3}{8}$, $\frac{5}{13}$, &c., may be shown by the following experiment:—

Take a number of spheres (say oak-galls) to represent embryo-leaves, and attach them in two rows in alternate order ($\frac{1}{2}$) along opposite sides of a stretched india-rubber band. Give the band a slight twist, to determine the direction of twist in the subsequent contraction, and then relax tension. The two rows of spheres will roll up with a strong twist into a tight complex order, which, if the spheres are attached in close contact with the axis, will be nearly the order $\frac{1}{3}$, with three steep spirals. If the spheres are set a little away from the axis, the order becomes condensed into (nearly) $\frac{2}{5}$, with great precision and stability. And it appears that further contraction, with increased distance of the spheres from the axis, will necessarily produce the orders (nearly) $\frac{3}{8}$, $\frac{5}{13}$, $\frac{8}{21}$, &c., in succession, and that these successive orders represent successive *maxima* of stability in the process of change from the simple to the complex.

It also appears that the necessary sequence of these successive steps of condensation, thus determined by the geometry of the case, does necessarily exclude the non-existent orders $\frac{1}{4}$, $\frac{3}{7}$, $\frac{4}{9}$, $\frac{4}{11}$, &c.

Numbering the spheres from 0 upwards, it appears that, under contraction, the following numbers are brought successively into contact with 0, alternately with right and left:—1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, &c. None of them stands vertically above 0 while in contact with it, but a little to the right or a little to the left, and so far the results of this experiment fall short of the perfect fractions $\frac{1}{3}$, $\frac{2}{5}$, $\frac{3}{8}$, $\frac{5}{13}$, &c.; but in this very failure the results of the experiment are more closely in agreement with nature than are those perfect fractions themselves, for those fractions give the angular divergence only in round numbers (so to speak), and lose account of the little more or the little less which makes all the difference between a vertical rank and a spiral. In the large majority of spiral-leaved plants, one has to be content with "$\frac{2}{5}$ nearly" or "$\frac{3}{8}$ nearly," and it is difficult to find a specimen in which the fraction represents the order exactly.

The geometrical relations of the members of the above series 1, 2, 3, 5, 8, 13, &c., are as simple as their numerical relations.

Analysis of the order seen in the head of the sunflower, and other examples, by consideration of their several sets of spirals, presents striking agreement with the above synthetical process. In the sunflower, a marginal seed taken as 0 is found to be in contact with the 34th, the 55th, and the 89th (counted in order of growth), and even with the 144th,, if there is not contact with the 34th. The dandelion, with a lower degree of condensation, has 0 in contact with the 13th, the 21st, and the 34th in large specimens. The house-leek in its leaf-order has 0 in contact with the 5th, 8th, and 13th. The apple-bud has 0 in contact with the 2nd, 3rd, and 5th; and thus we see that in nature the very same series of numbers is found to have contact-relation with 0, which we have already seen possessing that relation in the experimental condensation of the order $\frac{1}{2}$.

Difference of leaf-order in closely-allied species (e.g. *Plantago major* and *P. Coronopus*) is found in close relation to their different habits and needs.

The prevalence of the order $\frac{1}{2}$ in marine *Algæ*, and in *Gramineæ*, a low-developed gregarious group, and its singular freedom from individual variation in that group and in elm, beech, &c., support the view that this order is the original of the spiral orders.

In many plants we find actual transition from the order $\frac{1}{2}$ to an order more complex, as, for instance, Spanish chestnut, laurels, nut, ivy,—and these instances agree in presenting the complex order in the buds that occupy the most exposed situations, while they retain the simple $\frac{1}{2}$ in the less exposed lateral buds. Several kinds of aloe have the order $\frac{1}{2}$ in their basal leaves and a higher order in the remainder. A species of cactus often contains a complete epitome of phyllotaxy in a single plant or even in a single shoot.

Shoots of acacia often present a zigzag disposition of their leaves, on either side of the branch, which seems unintelligible except as a distortion of an original two-ranked order.

The prevalent two-ranked arrangement of rootlets or roots seems to be a survival underground of an order which originally prevailed through the whole plant, root, stem, and branch.

In the whole Monocotyledonous class, the first leaves in the seed have the order $\frac{1}{2}$. In the Dicotyledonous class the first leaves in the seed have the simplest order of the whorled type.

As the spiral orders have probably been derived from a two-ranked alternate arrangement, so the whorled orders have probably been derived from a two-ranked *collateral* (two abreast) arrangement. This is illustrated by an experiment similar to the former, and it is seen that successive parallel horizontal pairs of spheres are compelled under contraction to take position at right angles to one another, exactly in the well-known crucial or decussate order. These whorls of two contain potentially whorls of three and four, as is seen in variations of the same plant, but the experiment does not show the change.

The reason of the non-survival of the (supposed) two-ranked *collateral* order lies in its manifest instability, for under lateral pressure it would assume the alternate, and under vertical the crucial order.

The bud presents in its shape a state of equilibrium between a force of contraction, a force of constriction, and a force of growth.

To sum up, we are led to suppose that the orignal of all existing leaf-orders was a two-ranked arrangement, somewhat irregular, admitting of two regular modifications, the alternate and the collateral; and that the alternate has given rise to all the spiral orders, and the collateral to all the whorled orders, by means of advantageous condensation in the course of ages.

ON THE SPECTROSCOPE AND ITS APPLICATIONS

V.

SPECTRUM analysis, then, teaches us this great fact, that solids and liquids give out continuous spectra, and that vapours and gases give out discontinuous spectra ; that is to say, that we get bright lines in different parts of the spectrum, instead of having an unbroken light all over the spectrum. I might vary this statement by stating broadly that the radiation or giving out of light by solids and liquids is a general one, and that the radiation or giving out of light by gases and vapours, instead of being general, is in the main a selective one.

The tubes, to which reference has already been made, put us then in complete possession of a point which has already been arrived at by two different lines of investigation. A few years ago Dr. Frankland, in investigating the spectrum of hydrogen, which, as you know, according to the statement I have just made, ought to give a discontinuous spectrum, discovered that, when observing the spectrum under very great pressure, he got a white light, and a continuous spectrum. Afterwards Dr. Andrews, another fellow of the Royal Society, who was working at the theory of vapours and the theory of liquids from a perfectly different stand-point, and who never thought of using a spectroscope at all, arrived at the conclusion that it was quite possible that vapours might be so condensed in almost every case, that by crushing them together, so to speak, you might really arrive at a liquid form of the vapour which you might choose to investigate. I hope you will not think that these high physical investigations are not practical enough. Let me remind you that we do not know what they may lead to.

Not only did Dr. Frankland determine that very dense gases and very dense vapours gave continuous spectra, but in another research, in which I have had the honour of being associated with him, we have shown that the spectrum of a vapour or of a gas does very much more than tell us merely what the gas or vapour experimented upon is ; it in fact tells us something of the physical condition of that gas or vapour, that is to say, whether it is very rare or whether it is very closely packed together—whether it exists under a low or a high pressure. Very fortunately for us, this is an investigation which has not only an immense application in every chemical experiment with which the spectroscope has to do, but it has its story to tell and its aid to give concerning every star that shines in the heavens. We may state generally that, beginning with any one element in its most rarefied condition, and then following its spectrum as the molecules come nearer together, so as at last to reach the solid form, we shall find that spectrum become more complicated as this approach takes place, until at last a vivid continuous spectrum is reached.

Spectrum analysis, then, if it merely differentiated between gases, vapours, solids, and liquids, and between gases and vapours in different states of pressure, would really be a new chemistry altogether ; and I have no doubt that the time is not very far distant when, not only in the chemist's laboratory, but in a great many applications of the physical sciences, the spectroscope will be considered as necessary, and will be almost as much used, as a chemical balance, and the sooner that time comes the better.

But not only are we able to differentiate between different bodies, but the most minute quantities of substances can be determined by this method of research. The thing seems so impossible, that you may, some of you, feel inclined to doubt my assertion when I tell you, for instance, that Kirchhoff and Bunsen have calculated that the 18-millionth part of a grain can be determined by the spectroscope in the case of sodium ; that is to say, if in anything which I choose to examine by means of my spectroscope the quantity of sodium present amounts only to the 18-millionth of a grain, the spectroscope is perfectly competent to take up that minute quantity, and bring it out into daylight, so as to be detected with certainty. This reaction of sodium is so delicate, that if we examine any flame, burning in air, we almost invariably find sodium in it, for every particle of dust is impregnated with a sodium salt, probably sodic chloride. This is not to be wondered at, as two-thirds of the earth's surface is covered by sea, which contains a considerable amount of sodium salts, and the fine spray, which is continually caused by the dashing of the waves, evaporates and leaves *minute* specks of salt which are carried over the whole land, and make themselves visible in our spectroscopes. Take another instance. Lithium is a substance the knowledge of the existence of which as a common element we owe entirely to the spectroscope; the 6-millionth part of a grain of this can be detected. If we examine anything for lithium, and do not get the characteristic red line, we know that not even the 6-millionth of a grain is present. Strontium, again, can be discovered if only a millionth part of a grain is present. So much for the great power of spectrum analysis in its physical applications, and its dealing with minute quantities of the elements which we know already, and this of itself would be of enormous importance.

But the spectroscope does not stop here ; it discovers the known elements under conditions where detection seemed almost impossible, and in which the old chemistry was powerless to help us. Let us take, again, for instance, lithium. Lithium was only known formerly to exist in four minerals ; it is now known, thanks to the spectroscope, to exist almost everywhere. If we were to take the ash of a cigar and introduce it into a colourless gas flame and examine the colouration with the spectroscope, we should get a spectrum of lithium ; and if we analysed in the same way the ash of milk, or the ash of blood, or of grapes, tea, sugar, &c., we should also find it. Dr. Miller has shown that, in the Wheal Clifford mine 800 lb. of this salt are given every 24 hours, though before the advent of spectrum analysis no lithium was known to exist there. It has also been found in meteoric stones, in the water of the Atlantic, &c. Surely this is an application of very great importance.

Another extremely important point about spectroscopic analysis is that, although we may have to analyse a complicated mixture of substances, the spectroscope is perfectly competent to deal with them. The characteristic lines for each element must stand out and be visible whether the substance be simple or complex. Thus, for instance, if we mix together some sodium and lithium, and place some of the mixture in a flame, we shall see nothing but the brilliant yellow colour due to sodium, the crimson flame of the lithium being entirely hidden. A moment's examination with the spectroscope, however, is sufficient to show us that both lithium and sodium are, without the slightest doubt, present in the flame ; for both the yellow and red lines stand out as distinctly as they did when the simple salts were experimented with. The presence of lithium, indeed, may be detected, even if it be mixed with ten thousand times its bulk of sodium compounds.

But, further, spectrum analysis is not satisfied with showing us sources of known elements. It discovers new elements altogether. In 1860, Bunsen happened to be examining with a spectroscope the result of one of his analyses of the waters of a spring near Dürkheim, and he saw some lines which he had never seen before, although he had very carefully mapped the spectra of the known elements. Bunsen, as you know, is a very resolute chemist, and what he did was this. Having faith in his instrument, he evaporated no less than forty-four tons of the water of this spring, and out of these forty-four tons he got about two hundred grains of what turned out to be a new metal, which he

called Cæsium. Rubidium was the next metal which was discovered in this way. Take another instance, the discovery of thallium by Mr. Crookes. Mr. Crookes was working with a seleniferous deposit from the Hartz mountains, when, by the aid of the spectroscope, he discovered this metal, which, I am informed, is now extensively used in the manufacture of fireworks. The spec-

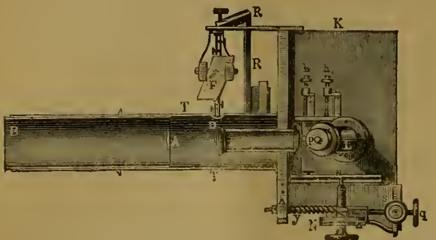

FIG. 27.—Side view of Star Spectroscope, showing the arrangement by which the light from a spark is thrown into the instrument by means of the reflecting prism *e*, by a mirror F.

trum of this metal is extremely distinct and beautiful, and you will understand why it has been named thallium, from the Greek word for a twig, on account of the beautiful green colour of the single line ordinarily visible.

A fourth element has been discovered by means of the spectroscope by two German chemists, Professors Reich and Richter, who were experimenting on zinc blend, and found two unknown indigo bands in the spectrum, which they successfully traced to the existence of a small quantity of a new metallic element, which has been named Indium.

You all know how important chemical analysis is in

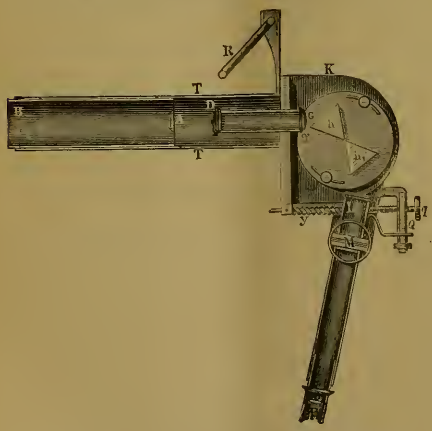

FIG. 28.—Plan of Star Spectroscope. T, Eye-piece end of telescope: B, Interior tube, carrying A, cylindrical lense: D, Slit of spectroscope; G, Collimating lens; *h h*, Prisms; Q, Micrometer.

thousands of things connected with the arts, manufactures, and commerce, in detecting adulteration for instance, and in these matters the spectroscope gives our chemists a power which was undreamt of a few years ago.

There is another very beautiful application of the spectroscope which perhaps many of you will say is of more practical importance than those I have already brought to your notice. You know that, in the Bessemer process five tons of cast iron are turned into cast steel in twenty minutes. Now steel is only cast iron minus some carbon. It is clear, therefore, that the process depends upon getting rid of the carbon. How then can the spectroscope aid us in determining the time at which the carbon is got rid of? Nothing is more easy. The heat from the incandescent iron is so intense that the vapour of the different substances mixed with it is visible above the retort in which the metal is placed, and we get, so to speak, an atmosphere of incandescent vapour surrounding the cast iron. When we examine these incandescent vapours by means of a spectroscope, it is found that the spectrum changes very considerably at different times during the combustion of this cast iron. Now it so happens, that the process of conversion is such a delicate one that a mistake of ten seconds either way spoils the whole five tons which are being operated upon. You

will see in a moment, therefore, that this is a case in which any rule-of-thumb or very rough method might now and then lead to a mistake; but when the spectrum of these incandescent vapours thrown out by the cast-iron is examined very carefully by means of a spectroscope, it is found that at the first the spectrum of carbon is quite visible, but at the right moment, which has been found by practice, that spectrum disappears, the combustion having been sufficient. All we have to do now, to ensure the charge being properly turned out, is, therefore, by means of the spectroscope, simply to watch certain lines in the spectrum, and when they show signs of disappearance say "Now," and the thing is done without any possibility of error. This is an instance of the practical application of the spectroscope in one direction; now let me give you one in another.

When Dr. Bence Jones wished to determine some

questions connected with chemical circulation, he employed the spectroscope with great success. Many of you, at the first blush, would be inclined to say it was not very likely that the spectroscope would help us here. If it were a question, for instance, of our own chemical circulation, we would not relish the idea of being converted into an incandescen vapour for the pleasure of testing a theory. But, fortunately, there are such things as guinea-pigs, and Dr. Bence Jones, by studying the vapours of the ashes of these animals, has arrived at some results of extreme importance. His *modus operandi* was as follows :—He gave the guinea pigs chloride of lithium, and then the question was to find, by burning the ashes of the different parts of the guinea-pigs, variously removed from the fountain of circulation and from the ordinary ducts of the body, to ascertain how long it took lithium to get absorbed into every part of the body. The most distant part, as far as circulation goes, is the lens of the eye. If, then, we give a guinea-pig chloride of lithium, then kill the guinea-pig, and examine the ash of the eye lens, say three hours after the lithium has been taken into the system, and if we find the lithium line in the spectrum of the ash vapour where no lithium was before, that is to say, if by means of the spectroscope we see that line which we have seen characterises the lithium spectrum, we know that the chemical circulation of the body is such as to take lithium through the body to that particular point of the circulation in that time. In the human subject Dr. Bence Jones has hit upon a very practical method of arriving at something like the same conclusion, by examining the spectra of the ashes of cataracts.

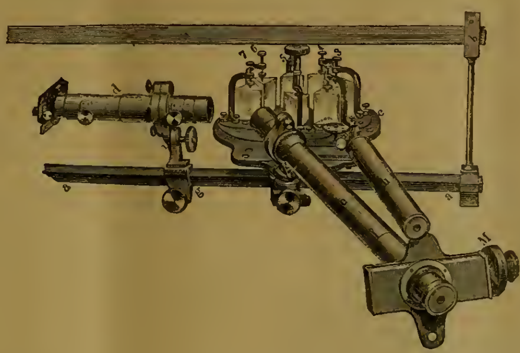

FIG. 31.—Sun Spectroscope. *d*, Collimator; *e*, Observing telescope ; *h* and M, Two micrometers ; 1, 2, 3, 4, 5, 6, 7, Prisms.

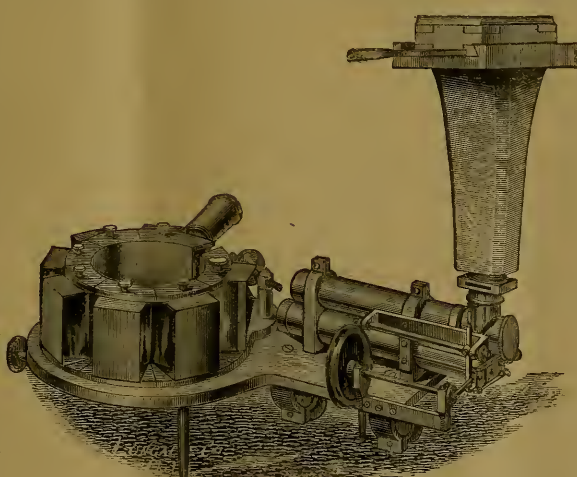

FIG. 32.—Sun Spectroscope arranged for photography.

So far as I have dealt with the applications of the spectroscope, up to the present time, I have dealt in the main with the application to chemistry and to physics, in other words, to the examination of light given out by terrestrial substances ; but I must now, with your permission, take you to the skies, reminding you that at present, I am merely dealing with the giving out of light, and with light emitted by celestial objects. We shall afterwards have to deal with the stopping or absorption of light, by vapours and other transparent media when the light passes through them.

I have already referred to the special fittings that were necessary for the application of the spectroscope to the telescope, and I think on carefully looking at the engraving (Figs. 27 & 28) representing a star spectroscope, you will see exactly how the spectroscope is applied to a telescope. We must now go a little more into details. One class of spectroscopes, as applied to telescopes, is arranged for observing the spectra of the stars, nebulæ, &c., and another with a much greater dispersive power for observing the spectrum of the sun.

In both spectroscopes the arrangements employed are similar, and resemble those of the instruments that have been already described. A finder on the side of the large telescope enables the image of the star to be brought on the slit, while, in the case of the sun, its image is received on the slit screen, and any part of the image may be brought on the slit by mere inspection.

The spectroscope is attached to the eye-piece end of the instrument, and the image formed by the telescope is received on the slit plate. Arrangements are necessary in the case of the star spectroscope for widening out the spectrum ; this is done by a cylindrical lens (as before explained); and for obtaining a spectrum of comparison, this is done by reflecting into the instrument the light emitted by an electric spark.

In the star spectroscopes, the number of prisms, and the consequent deviation and dispersion, is small. The accompanying woodcuts will make their detailed construction quite clear. In the case of sun spectroscopes,

the deviation and dispersion required are large, the deviation amounting to over 300°; that is to say, the ray of light is bent through almost a complete circle; the light from stars is dim, and many prisms cannot be employed to widen out the spectrum, but in the case of the sun, there is light sufficient to give us a bright spectrum after it has been enormously dispersed.

Figs. 31 and 32 show a very powerful spectroscope to be attached to the telescope for observing the spectrum of the sun. One peculiarity of the instrument in Fig. 33 is that the ray of light having passed once through the lower part of the train of prisms, is received by a right-angled prism, which totally reflects the light twice, sending the ray of light back through the upper part of the same prisms, when it is again refracted; we thus have, by using these prisms, the same effect as if thirteen prisms had been employed. The ray of light enters the

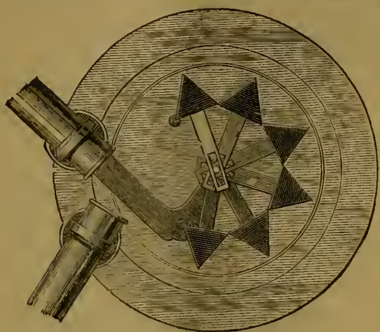

Fig. 33.—Automatic arrangement for securing the minimum deviation of the observed ray.

instrument by the lower tube, and after passing first through the lower half of the prisms, and back through the upper half, is received in the upper tube, and reflected upwards for convenience of observation. These prisms are so arranged, that whatever part of the spectrum is being observed, they are always at the angle of minimum deviation for this part of the spectrum, a very important point, as if this is not attended to the spectrum loses much of its brilliancy and sharpness. This is done either by attaching the prisms to a spring of ebonite or gun metal moving on a fixed point near the first prism of the series, as in the arrangement shown, or each prism may be attached to a radial bar acting on a central pin, as shown in Fig. 33. J. NORMAN LOCKYER

(To be continued.)

HUNTERIAN LECTURES BY PROF. FLOWER

LECTURES IV. V. VI.

IT will not be necessary in describing the fossil remains of mammalia to devote any time to the consideration of the Monotremata, for though it might have been supposed that these animals, the Echidna and Duck-bill, on account of their being the lowest in the scale, would have been largely represented in ancient times, evidence to that effect has not been forthcoming. In the post-pliocene of Australia, the lower end of the humerus of a large Echidna, was found by Mr. Krefft, curator of the Museum at Sydney, and that is apparently the only recorded specimen from the class. With regard to marsupial animals the case is very different, and the remains prove that their geographical distribution formerly was not at all what it is now, when they are confined to Australia, the Austro-malay Archipelago, and South America. The family may be classified by the teeth or by the feet. According to the former method the Kangaroos, Phalangers, Koalas, in which there are only two lower incisors, without persistent pulps, form one herbivorous group; the Wombats a second; and those with more than two lower incisors, including the Bandicoots, Dasyures, Thylacine, and Opposums, a third carnivorous section. If the structure of the feet be taken as the main point, the tendency to the reduction of the second and third digits places the Bandicoots with the Kangaroos, instead of with the Dasyures, and does not otherwise modify the arrangement. The at first sight great difference between the molar teeth of the Thylacine and the Kangaroo can be easily bridged over by a comparison of intermediate forms; looking for instance at an upper molar in the latter, its crushing surface presents two broad ridges, with an intermediate depression, in which there is an oblique groove. In the Thylacine there is a central large, and two lateral smaller tubercles, with a band connecting the medium with one of them. There is also a small posterior and two very small anterior tubercles in the cingulum. In Perameles the molar presents two rows in a double crescent, in front of which are four minute processes, which represent those of the cingulum of the Thylacine, the crescents being representatives of the big tubercles. In the Kangaroo Rats the tubercles alone remain, and in the Kangaroo these blend to form the ridges.

Respecting the fossil forms, those from the Purbeck beds have been thoroughly worked out by Prof. Owen. With the exception of *Plagiaulax* they belong to the polyprotodont division, and nearly all have more than seven teeth of the molar series, *Triconodon* and *Triacanthodon* being the exceptions, they also being peculiar and differing from all existing Marsupials in having four premolars and three molars. There is no evidence to show whether there was any succession of the teeth. *Plagiaulax* has been the subject of one of the most important controversies in connection with palæontology, between Prof. Owen and the late Dr. Falconer, the former maintaining that it was carnivorous, eating the lizards found with it; Dr. Falconer that it was herbivorous and allied to *Hypsiprymnus*. The fact of its having only two lower incisors, and that the molars are hypsiprymnine in form tends to show that it must have had some relation to the herbivorous group, and shows that at so ancient a date the family had already divided in the manner that we now find it.

The tertiary Marsupialia must next be considered. In the Eocene gypsum of Montmartre several small skeletons have been found, clearly referable to the Opossums, and with a similar dentition, from which Cuvier was able to classify them correctly and predict the existence of marsupial bones in the uncovered skeletons. From Auvergne three similar Eocene species have been described, and in England Mr. Charlesworth has, on undoubtedly insufficient evidence, referred a premolar to the same genus, Dideiphys. The Yale College expedition have obtained, among the large number of bones that they have collected, some which Prof. Marsh thinks are Marsupial. In the Pliocene there have not been any fossil remains of this sub-class yet obtained, but many in the Quaternary period. In the Brazilian caves Opossums have been found in abundance, and in the Wellington Valley and many other parts of Australia extremely interesting forms have been obtained, which must be referred to more fully. Prof. Owen has studied them in great detail. The remains may be divided into two divisions; (1), those allied to existing genera; and (2), those not now represented. With regard to the former it is interesting to observe that the Thylacine and Ursine Dasyure, now restricted to Tasmania, at one time abounded on the mainland. There are also remains of enormous Wombats and

Kangaroos, and the Kangaroo-rats were well represented. Of the genera now unrepresented *Diprotodon* was one of the largest; it was the size of the biggest existing Rhinoceros; only one species is known. Excepting the skull the bones are not well known, the feet and several other parts not having been obtained. There was a strong descending process from the zygoma. The dental formula is represented thus: i. $\frac{3}{1}$. c. $\frac{0}{0}$. m. $\frac{1+4}{1+4}$. The middle anterior incisors and those of the lower jaw closely resemble those of the Rodentia on a large scale; they grew from persistent pulps. The upper lateral incisors were small and had closed roots. Between them and the molars there was a gap. The molars were double crested, with four roots in the upper and two in the lower. Its dentition allies it with the Kangaroo, but from the bones that are known it is probable that its proportions were more that of the Wombat, the femur being longer than the tibia, and of the same length as the humerus. The femur was singularly compressed. Another genus, *Nototherium*, was still more extraordinary; it was first supposed to have no lower incisors, but this was subsequently proved to be incorrect. Mr. Macleay, after Prof. Owen's description of the genus from lower jaws only, obtained upper jaws of an animal, called by him *Zygomaturus*. Prof. Owen stated, and apparently with very good reason, that this was nothing but the upper part of the skull of his *Nototherium*. In this genus the zygoma is enormous in all directions and at the extreme anterior root has a descending process. Its dental formula is i. $\frac{3}{1}$. c. $\frac{0}{0}$. m. $\frac{5}{5}$, resembling Diprotodon, except that the incisors in upper and lower jaws are all rooted. Three species have been described, and no bones of the body have been found. In the museum of the College there is an astragalus, very Wombat-like, and also an atlas which agree well in size with what would have been expected in such an animal, which for other reasons was probably intermediate between the Kangaroos and Wombats.

Thylacoles is the last of these extinct marsupials; none of the bones, except of the head, have been found; the zygoma and the angle of the lower jaw are still unknown. As far as can be determined, it apparently approaches nearest to the koala. The teeth are quite peculiar to the genus; the dental formula is i. $\frac{1}{3}$. c. $\frac{1}{0}$. p.m. $\frac{3}{1}$. m. $\frac{1}{32}$. The incisors in both jaws are much as in the phalangers, the median being large and with closed roots. Then follow two small lateral teeth in the upper jaw, behind and *internal* to which is an almost hidden canine, partly covered posteriorly by two small premolars. The characteristic tooth, an enormous elongated and flattened last premolar comes next. This peculiar tooth is evidently that which replaces the only one lost in this class of animals, and which is always large, particularly in the kangaroo-rats. Internal to the posterior border of this tooth the minute true molar stands, just as in the cats. In the lower jaw two rudimentary teeth are sometimes present, followed by the peculiar large premolar, and that by two small molars. The muzzle was blunter than in most existing diprotodonts. The stunting of the molars is correlative with the great development of the extraordinary premolar undoubtedly. Prof. Gervais has taken a cast of the interior of the skull, and considers that the brain approaches the wombat most nearly. Prof. Owen originated and still strongly supports the idea that *Thylacoles* "was one of the fellest and most destructive of predatory beasts." Mr. Krefft, of Sydney, was the first to call his opinion in question, and he gave a conjectural restoration of the then unknown anterior part of the skull and incisor teeth, which subsequent discoveries have in great measure confirmed. No doubt its nearest alliances are with the phalangers and kangaroos, which are neither of them carnivorous. In the carnivorous marsupials, as in the cats, the canines are large and the incisors small. It is probable that the uniqueness of the dentition indicates a peculiar diet, perhaps some form of food, of a vegetable nature, which has disappeared, as has its consumer. Claws have been found, probably of this animal; they closely resemble those of the phalangers.

NOTES

Dr. Debus has been appointed Professor of Chemistry at the new Naval College.

It is rumoured that Prof. James Thomson of Belfast wil succeed to the Chair of Engineering at Glasgow University, vacant by the death of Prof. Macquorn Rankine.

Sir John Lubbock will, to-night, at half-past eight, lay before the Society of Antiquaries the results of his researches during a tour last autumn respecting the site of Troy.

According to a Berlin telegram, another coal-field of apparently gigantic dimensions has been discovered in Central Asia—the Chodshent district, near Sir Darya.

The *Times* understands that an intense magneto-electric light and an exceedingly powerful gaslight will shortly be exhibited machine moved by steam power, which a high authority in this simultaneously on the north and west sides of the upper part of the Westminster Clock Tower. The current in the former will be generated by a comparatively novel and remarkable magneto-electric country pronounces to be a decided step in advance of every otl er machine of the kind. The latter is in operation at various lighthouses on the Irish coast, and may in favourable weather be seen at the distance of twenty-five miles. The exhibitors have proposed that the trial shall be made at their own cost, except in very trifling particulars.

We learn with regret that Mr. J. Glaisher, F.R.S., has resigned the secretaryship of the Meteorological Society, an office which he has held continuously (except during his presidency) from the foundation of the society, of which he was one of the earliest promoters, in 1850.

The Vice-Chancellor of Cambridge has appointed Prof. Tait, of Edinburgh University, Rede Lecturer for the ensuing year. Prof. Tait will deliver his lecture in the Easter term.

An influential committee has been formed at Cambridge of members of the University and others for the purpose of having a portrait of Prof. Cayley painted and presented to Trinity College. A considerable portion of the sum required has been already promised. The portrait, which is being painted by Mr. Lowes Dickenson, is of the same size as that of Sir William Thomson, by the same artist, that has been recently placed in the Combination Room of St. Peter's College. The movement is supported by all members of the University, irrespective of college, and other admirers of Prof. Cayley's mathematical discoveries; the only reason for the presentation of the portrait to Trinity (the professor's own) College being that there is no public building in the University appropriate for the reception of portraits of distinguished members of the University. Everyone will be pleased at the compliment which will thus be paid to the most illustrious English mathematician of the age. Subscriptions may be sent to the treasurer, William Walton, Esq., Trinity Hall.

At the Annual Meeting of the Geological Society on February 21, the Wollaston Gold Medal was awarded to Sir Philip de Malpas Grey-Egerton, Bart., F.R.S.; the balance of the proceeds of the Wollaston Donation Fund to Mr. J. W. Judd, F.G.S.; the Murchison Medal to Mr. William Davies, of the British Museum; and the balance of the Murchison Fund to Prof. Oswald Heer of Zürich.

WE learn that the University of St. Andrews has conferred the degree of LL.D. on Mr. E. B. Tylor, author of "Primitive Culture."

THE Royal Commission for Scientific Education and the Advancement of Science still continue their sittings.

AT the general monthly meeting of the Royal Institution this week at which Prof. Tyndall was present for the first time since his return from America, a resolution was unanimously adopted congratulating the Professor upon his safe arrival in England, expressing satisfaction that the people of the United States had shared in the advantages of his teaching, cordially welcoming him on his return to his own scientific home, and wishing him continued health and prosperity. Prof. Tyndall was also thanked for his generous gift to the Institution of the splendid and extensive apparatus employed by him in his lectures in America, and congratulated on the liberal spirit, and the love of science, which has led him to appropriate the profits of his lectures in the United States to the establishment of a fund to assist the scientific studies of young Americans in Europe.

DR. PETERMANN has received news from Africa that Mikluchs Maclay, the Russian Traveller who was believed to be dead, is alive and well in New Guinea.

PHYSICAL science in America has experienced a great loss in the death, in the sixty-seventh year of his age, of Prof James Henry Coffin, of Lafayette College, this sad event taking place on the 6th of February. Prof. Coffin was a native of Massachusetts, and for a time a professor in Williams College, where he planned the construction of Greylock Observatory on Saddle Mountain. He became a member of the faculty of Lafayette College in 1846, where he has since filled the chair of mathematics and astronomy. Prof. Coffin is best known from his treatise on the "Winds of the Northern Hemisphere," published by the Smithsonian Institution in 1851. At the time of his death he was engaged in a second edition of this work, brought down to the present day, and extended so as to embrace the entire globe. He was a member of the National Academy of Sciences. It is quite a curious coincidence that Captain Maury and Prof. Coffin, who have given so much attention to the subjects of atmospheric currents, should have died within a week of each other, and at the same age.

WHEN is the foundation-stone of our grand new Natural History Museum to be laid? Is Government waiting for the advent of fine weather in order that the ceremony may be as auspicious and imposing as possible? We can hardly believe the current gossip that the fiscal authorities of the country have quietly retired the thousands said to have been voted for the purpose, in order that a saving might be effected in their expenditure, and a handsome surplus be vaunted of in the forthcoming budget. Meanwhile see what our young, energetic, long-headed cousins on the other side are doing. A new Natural History Museum is about to be erected in New York 800 feet long by 600 wide, which will be the largest building in America. 100,000*l.* was voted last winter by the legislature to commence it, and 200 men are already blasting for its foundations. It is eventually to cost 2,000,000*l.* sterling, and fifteen years will be occupied in its construction. This great building is to cover fifteen acres of ground, and is to be situated on Montallan Square, facing Eighth Avenue and Central Park. The front portion is to be finished directly, and the back portion is to be finished from time to time as needed, and as appropriations are made for it. The material is to be granite. The building is to be four stories high, with students' rooms in the upper story, and rooms and shelves for specimens illustrating natural history, zoology, botany, and mineralogy, on the ground floors. The architecture of the building is to be a kind of French *Renaissance*, similar to the Luxembourg or the buildings around Fontainebleau.

A MAGNIFICENT present of Peruvian skulls has lately been received by the Anthropological Institute from Consul Hutchinson of Callao. This highly instructive series consists of 150 specimens dug out- not gathered from the surface—of the old aboriginal burying grounds of Pasamayo and of Ancon, 20 and 30 miles north, and from Cerso del Oro about 100 miles south of Callao. Twenty-four of these were taken by the Consul himself from the Huacas of Ancon, and are probably those of Chinchas or perhaps Aymaras. We recommend all anthropologists to take the opportunity now afforded for a few days, of visiting the collection which may be seen daily from 12 to 4 at the rooms of the Institute. It is expected that the President (Prof. Busk) and Dr. Barnard Davis will each contribute notes on the more remarkable of the skulls at the meeting to be held on the 18th inst.

PROF. VAN DER SUNDE BAKHUYZEN has been appointed to the directorship of the Leyden Observatory, the head-quarters of Dutch astronomy, as successor to the late Prof. Kaiser, whose death we noticed in NATURE, vol. vi. p. 354. Prof. Bakhuyzen was a pupil of Kaiser's.

WE hope shortly to give a brief notice of some recent works on the Echinoderms, but in the meanwhile it may be well to mention that the following important contributions to our knowledge of this group have within the last few weeks been published. (1) Illustrated Catalogue of the Museum of Comparative Zoology at Harvard College. No. vii.—Revision of the Echini; parts 1 and 2 with forty-nine plates. Part 1 contains Introduction, Bibliography, Nomenclature, Chronological List, Synonymy, Geographical Distribution; Part 2 contains Echini of the eastern coast of the United States. (2) "Ophiuridarum novarum vel minus cognitarum descriptiones non nullæ," by Dr. C. Lütken. In this there is a most interesting chapter on spontaneous division in star-fishes. (3) On the Ophiuroids collected by Dr. Goës in the Josephine Expedition, with a Conspectus generum Ophiodermatidarum, by A. Ljungman. (4) A modest catalogue of the Echinodermata of New Zealand, with diagnoses of the species, by Captain F W. Hutton. The first memoir in this list will mark an era study of the Echini.

PROF. HYATT, of Cambridge, Mass., by means of sections of the central spirals of Ammonites and Goniatites, has been able to obtain some valuable results on the subject of the Embryology of Fossil Cephalopods. He finds that the shell in its first stage is represented by a globular sac, which is not retained in Nautilus. Into this sac opens the first whorl of the shell, and the others are coiled round it. Prof. Hyatt has endeavoured to prove that the series of forms, so well known as depending on the amount of coiling or uncoiling of an elongated cone, is epitomised in the life of the individual Nautilus or Ammonite, the young being at first uncoiled, and the different degrees of coiling up finding a permanent expression in the genera of Ammonitidæ.

ORNITHOLOGISTS will be glad to hear that a new Indian ornithological journal entitled *Stray Feathers*, has just been started by Mr. Allen Hume, and published at Calcutta. The introductory number contains the first of a series of articles by the Editor, on the birds of Sindh, which will be welcomed by many. It also includes the first draught of a "Conspectus of the Avifauna of India and its dependencies," now in course of publication.

THE discovery of the African money cowrie (*Cypræa moneta*) in the barrow graves of Pomerania, in 1868, has had the effect of exciting much speculation among archæologists, as to the mode

in which they could have been introduced into the country. Some twenty-seven of them were found in an earthen vase mixed with earth and sand, each one being notched so as to permit its being arranged with others upon a string. Wagner is of the opinion that these shells must have been brought by the Phœnicians for the purpose of bartering with the people for amber. A closely allied species (*C. pantherina*) was found in graves in Swabia, which could not in any way have been associated with the Phœnicians. Jeitteles also mentions the occurrence, among certain prehistoric objects found near Olmütz, of a coral from the Indian Ocean, found very rarely in the Mediterranean.

MR. EDWARD A. BLYDEN has lately presented to Governor Hennessy, of Sierra Leone, a report of his mission to Falaba, in Africa, early in the year 1872. His route carried him through a considerable portion of the less-known region of Eastern Africa, and much information was derived, which it is proposed to embody hereafter in a detailed work.

THE report of Major Powell of his survey along the Colorado of the West, during the year 1872, has just been printed by the U.S. Congress, and embraces as its most striking feature an account of a remarkable series of folds and faults in the earth's strata, of the highest interest to the geologist. Numerous practical results of value are recorded, especially the discovery of coal, salt, and metals. Very large collections of special ethnological interest were gathered. An appropriation of 20,000 dols. is asked for by the Major to continue the work during the current year.

A BILL is now before Congress providing an appropriation of 20,000 dols., or as much thereof as may be necessary, for the purpose of having printed, at the government printing office, one thousand copies of the "Descriptive Anatomical Catalogue of the Army Medical Museum."

MR. JOHN MUIR, in the *Overland Monthly*, announces the existence of actual glaciers in the Merced group of Californian mountains, and remarks that the snow banks of Mounts Lyell and M'Clure, of the Yosemite region, are true glaciers as shown by the forward movement of stakes planted by him across the bank. The central stakes were found to move forty inches in forty-six days, while the surroundings exhibit all the peculiarities of glaciers in the form of moraines, &c. The Mount M'Clure glacier is about half a mile in length, and of the same breadth in the broadest part, and the Mount Lyell glacier is about a mile long.

A BILL has passed one branch of the Legislature of Michigan establishing a commission of fisheries, and appropriating 10,000 dols. for two years for purposes connected with the increase of food fishes in the State.

IN the *Australian Mechanic* for December, a proposal is mooted for the formation of an association in the southern continent, similar to our own British Association.

WE learn from the same journal, that a society is in course of formation in Victoria, on the basis of the London Society of Arts.

ON Feb. 9 there was a shock of earthquake at Antioch.

ON February 10 there were earthquake shocks felt at Durazzo in Turkey, and the 11th at Kavalla in Macubria, and on the 12th at Jajat also in Turkey; these were serious in their consequences.

ON Feb. 14 there was an earthquake at Sour (Tyre), Akka (St. John d'Acre) and Jerusalem. On the same day there was a hot stifling wind on the same coast, at Beiroot, which made breathing difficult. As the Imperial Meteorological Observatory at Pera, Constantinople, is now constituted under M. Coumbary, with the aid of widespread telegraphs, we shall get better records of the earthquakes over the large districts of the Turkish empire. Hitherto our information chiefly depended on the chance intelligence obtained by M. Charles Ritter, of the Ponts et Chaussées, and transmitted to Paris.

IN the *Calcutta Englishman* "A Bengalee" calls in question Mr. Darwin's statement that Bengalees shrug their shoulders. He says he remembers having seen several of his countrymen, who had adopted English ideas and habits, shrug their shoulders, but never has he observed it in any unsophisticated Bengalee. The remonstrance shows how widely the study of Mr. Darwin's works is disseminated.

A NEW Octopus has been added to the Brighton Aquarium, in room of the one whose unfortunate end we recently chronicled.

WE learn from *Les Mondes* that under the superintendence ot M. Geoffroy Saint-Hilaire, the sad havoc made during the late war upon the Paris *Jardin d'Acclimatation* has been nearly repaired. The collection of animals now numbers 6,148 head, valued at 158,370 francs; very nearly 5,000 animals have been added during 1872. The number of visitors during the past year has been 238,000.

A PRELIMINARY meeting of skilled workmen was held on March 1, at the offices of the Working Men's Club and Institute Union, at which it was decided to form a Trades Guild of learning, with a view of enabling skilled workmen to acquire a knowledge of history, political economy, technical education, literature, science and art.

WE learn from the *Journal of Botany* that Dr. Ernst of Caracas has been named by the Government of Venezuela to fill the chair of botany in the University of Caracas, where Natural History has hitherto never been taught. He is likewise commissioned with the foundation and management of a small botanic garden and the correspondent botanic museum. For the garden he will have the two large yards of the University building, both together 1,300 square metres large, which will give about 800 square metres available ground for planting.

A CATALOGUE is printed by M. Rodembourg, head-gardener, and M. E. Morren, director of the botanic garden belonging to the University of Liége, of upwards of 200 species of the interesting order *Bromeliaceæ* cultivated in it,—an evidence of the zeal with which scientific botany is pursued in some quarters on the Continent.

WE see from the *Ceylon Observer* that that paper has been attempting to run a "pigeon express" between Galle and Colombo, and would very likely have succeeded, had not a bloodthirsty civet-cat wriggled herself between the narrow bars ($1\frac{1}{2}$ in. apart) of the dovecot, and killed off five of the finest pigeons in training; in every case it had cut the jugular vein and sucked the blood. The *Observer* hopes, however, that ere many weeks other pigeons, now in training, will be regularly bringing from Galle to Colombo the budgets of news, written and printed on thin paper for the special purpose.

THE additions to the Zoological Society's Gardens during the last week include a Rose hill Parrakeet (*Platycercus eximius*) and a Crested Ground Parrakeet (*Calopsitta novæ-hollandiæ*) from Australia, presented by Mr. Griffiths Smith. A Crested Screamer (*Chauna chavaria*) from Buenos Ayres, presented by Mrs. Wilson. Two Black-eared Marmosets (*Hapale penicillata*) from Brazil, presented by Mrs. Bischoffsheim. A White-throated Capuchin (*Cebus hypoleucus*) from the U.S. of Colombia; a Puma (*Felis concolor*) from Cartagena; an Ocelot *Felis pardalis*) from Savanilla; and a Prince Albert's Curassow (*Crax Alberti*) from Cartagena, purchased.

THE THEORY OF EVOLUTION IN GERMANY

PROF. HAECKEL, of the University of Jena, may be regarded as the most eminent living representative of the doctrine of evolution in Germany. He has won a name for himself during the last ten years as the author of several remarkable works in various sections of Natural History; specially should be mentioned his monograph on the *Radiolaria* (Berlin, 1862), which is, according to Huxley, one of the most solid and important contributions to zoology that have appeared for a long time. We owe also to him a monograph on the Monads (*Journal de Jena pour la Médecine*, &c., 1868), the simplest of known organisms, and another on the *Geryonidæ* or *Hydromedusæ* (Leipzig, 1865); a history of the development of the *Siphonophoræ*, a work crowned by the Academy of Utrecht (1869); a paper on the Sarcode bodies of the *Rhizopoda* (in the *Journal de Zoologie Scientifique*, Leipzig, 1865); "Considerations on the Division of Labour in Nature and among Men" (in the collection of scientific treatises of Virchow and Holzendorff, 1869); and an essay on the "Origin and the Genealogical Tree of the Human Race" (in the same collection, 1868; 2nd edition, 1870). There has just appeared a monograph on the Calcareous Sponges (See NATURE, vol. vii. p. 279), on which the author has been engaged for five years. But his principal work is undoubtedly his "Morphology of Organisms," in which he has condensed the result of all his researches, and unfolded his views on Nature as a whole, its history, its constitution, and its development: it is a learned treatise on natural philosophy, in which the author has adopted out and out the system of Darwin. Indeed, on more than one point he goes much farther than his master, and does not shrink from any of the extreme consequences of principles which are simply stated by the English philosopher: it may with truth be said that he is more Darwinian than Darwin himself. He aims, in fact, at filling up the chasm which separates the organic and inorganic kingdoms, and is inclined to endow with life everything that has being, down to crystals and the smallest molecule of matter. Haeckel, with his comprehensive and philosophic mind, has more than once applied the theory of evolution to certain moral phenomena, and notably to politics, while Darwin has always shown considerable reserve in this direction. With respect, also, to the simian origin of man, he is much more explicit and precise than the English naturalist. In short, as he does not confine himself simply to the exposition of theories and principles, as he seeks to recover the marks of development in the particular genealogy of animal and vegetable organisms, he is compelled to commit himself to a great number of hypotheses, whose boldness it is impossible to deny. We do not speak thus in the way of reproach; we are none of those who think that science can live on experiment alone; hypothesis has always preceded experiment, and has seemed to incite and throw light upon it; it is the torch of induction, and without it the human mind would be doomed to sterility. Goethe has truly said that bad hypotheses are better than none at all. All that we ought to insist on is, that a hypothesis be abandoned the moment it is found to contradict certain facts, or when the same facts are more satisfactorily explained by a new hypothesis. One hypothesis may be better than another in three points—(1) when it accounts for a greater number of facts; (2) when it explains them by a smaller number of causes; and (3) when it makes use only of known causes, and involves a smaller number of accessory hypotheses. This is why Darwinism is preferable to supernatural hypotheses; it only applies to the whole round of natural phenomena causes which undoubtedly explain particular facts—natural selection, adaptation, and heredity.

Haeckel has with justice observed that if the doctrine of evolution has not yet been universally adopted, it ought to be attributed to the want of philosophic culture on the part of the great majority of contemporary naturalists; and this reproach is specially deserved by France, where Darwinism has hitherto been much less understood than in England and Germany. "The numerous errors of speculative philosophy during the first thirty years of our century have brought such discredit on philosophy as a whole among the advocates of the exact and empirical method, that the latter at present labour under the strange delusion that the edifice of the natural sciences can be built up by means of facts alone without philosophic connection,—with simple notions unenlightened by any general conception. If a purely speculative work undisturbed by the indispensable conditions of empirical facts is a chimerical edifice whose inanity is exposed by the first experiment, on the other hand, a purely empirical doctrine, composed exclusively of facts, is only a formless heap, unworthy of the name of structure. Rough facts are not the only materials; philosophic thought alone can rear them into a science. From this absence of the power of philosophising among naturalists proceed those gross mistakes in the elements of logic, that incapacity to draw the simplest conclusions, which are too clearly seen at the present day in all branches of the natural sciences, but particularly in zoology and botany." *

Haeckel has given a *résumé* of his theories as a whole in a series of lectures delivered at Jena in the Winter of 1867-68. These lectures have been re-published under the title of "Natural History of Creation" (Berlin, 1868; 2nd ed. 1870), in a volume which has already gone through several editions. What follows is an analytical exposition of the most important parts of this work. The three sections which immediately follow contain the substance of the 12th, 13th, 14th, and 15th lectures, which form a division of Haeckel's work under the title of "Principal Characteristics and Fundamental Laws of the theory of Evolution." Haeckel discusses those facts of Embryology, Palæontology, and Chorology, or the geographical distribution of living beings, which are calculated to throw light upon the science of the development of species.

Embryology

It is astonishing how much ignorance even now prevails upon the embryonic development of man and animals generally. Just as the originator of the theory of evolution—Lamarck—had to wait half a century before Darwin came to rescue his doctrine from oblivion, and impart to it new life, so Wolff's theory of Epigenesis, published in 1759, remained almost unknown till 1803, when there appeared Oken's "History of the Development of the Intestinal Canal." It was only then that the study of Ontogenesis began to spread, and soon there appeared the classic researches of Pander (1817), and Baer (1819). The latter especially, in a book which marks an epoch ("History of the Development of Animals"), has established the most important facts of the embryology of the vertebrates with so much intelligence and philosophic depth, that his doctrines have become the indispensable basis for the study of that group of animals to which men belong.

At the outset of his existence, man, like every other animal organism, is only an egg, a simple little cell, whose diameter is only one-fourth of a millimetre at the most. It differs from the primordial cellule of the other mammalia only in its chemical constitution and the molecular composition of the albuminous matter of which the egg essentially consists. And yet these differences cannot be directly perceived by any means at our disposal; but we are compelled by indirect conclusions to suppose their existence as the prime cause of the difference in individuals. The human egg encloses all the essential elements of a simple organic cellule: a protoplasm which bears the name of *vitellus*, and a *nucleus* or germinal vesicle. This nucleus is a small sphere itself enclosing another nucleus much smaller still, the *nucleolus*; exteriorly the protoplasm is enveloped by a membrane which is known by the name of *zona pellucida*. The eggs of many of the lower animals, as the greater part of the medusæ, are on the contrary naked cells, which do not possess this envelope.

As soon as the egg of the mammal is completely developed, it leaves the ovary and descends, by the narrow canal of the oviduct, into the uterus, where, after fecundation, it becomes an embryo. This transformation is thus brought about:—the original cellule becomes divided into two cellules; on the primitive nucleolus are formed two new specks, and the nucleus becomes separated into two vesicles, each of which takes with it half of the protoplasm. The result of this process is that in the heart of the vitelline membrane, which alone is not divided, two cellules are found in juxtaposition, differing from the original only in being unenveloped. Each of these new cellules is in its turn divided into two others, so as to form four, which in the same way become eight, these eight, sixteen, and so on; these successive segmentations producing an agglomeration of cellules, in outward appearance resembling a mulberry. The further development consists in these cells assuming the shape of a sac (*vesicula blastodermica*), in the interior of which a liquid collects; shortly, on a point of the wall which is composed of these cells

* Translated from an article by M. Léon Dumont in *La Révue Scientifique* for January 25, 1873.

* General Morphology, I. 63; II. 447.

is produced a disc-like coagulation; their number rapidly increases, and this particular condensation becomes the embryo strictly so called, while the remainder of the blastoderm serves only for its nourishment. The embryo soon begins to broaden into the form of a biscuit. Three leaves or layers of cellules can be distinguished, superposed like envelopes upon each other, and each having its particular place in the construction of the living being; from the exterior leaf is formed the epidermis and the central parts of the nervous system, the spinal marrow and the brain; from the central layer is formed the interior membrane which lines the digestive canal from the mouth to the anus, with all the glands that are attached to it (the lungs, the liver, the salivary glands, &c.); the intermediate layer is the source of all the other organs.

The processes by which the three layers of cellules give birth to the most complicated organs can all be reduced—(1) To new segmentations, and consequently to an increase in the number of the cells; (2) To the division of labour or the differentiation of these cellules; (3) To the combination of these cellules, differently developed. The cellules which comprise a living organism may thus be compared to the citizens of a state, some of whom have one set of functions to perform, others another; the division of labour, and the organic perfection which results from it, enables the state to accomplish certain undertakings which would be impossible to isolated individuals. Every living organism composed of many cellules resembles a sort of republic capable of accomplishing certain organic functions, which could not be discharged by a single cell, an *amœba*, or a monocellular plant. No rational mind would seek to explain by superhuman intervention the public weal which accrues to political society, from the harmony of particular actions; so also in the organism, all the adaptations to ends ought to be regarded as the natural and necessary consequence of co-operation, of the differentiation and the perfection of the cellules, and not as the intentional work of a supernatural will.

Until the brain begins to show itself distinctly, it is scarcely possible to recognise any difference between the embryos of the different vertebrata, or at least of the three superior classes—reptiles, birds, and mammals. Why, then, should any one now refuse to admit the most important consequence of the theory of evolution, according to which men have descended from simious or even inferior mammals? Are the phenomena of the development of the individual man, the earliest characteristics of which are given above, less marvellous? Is it not in the highest degree astonishing that all the vertebrate animals, belonging to the most diverse classes—fishes, amphibia, reptiles, birds, and mammals—cannot, in the earliest stages of their embryonic development, be distinguished from each other, and that even at a much later stage, when reptiles and birds are distinctly separated from mammalia, man and the dog are still almost identical? The development of the individual (*ontogenesis*) is as difficult to explain as that of the species (*Phylogenesis*). It may be even said that it is still more so, seeing that it has an infinitely shorter time in which to be accomplished. The former is nothing more than a compact reproduction of the latter, and Haeckel rightly finds in this parallelism the most incontestible proof in favour of the theory of evolution. Man and the superior vertebrata reproduce in the earlier phases of their development conditions which last through the life of the lower orders of fishes; they then pass into forms which are characteristic of the amphibia; the marks of the mammalia appear only at a later stage, and even here are discovered a succession of degrees which correspond to the characters of different species or families. It is the same order in which the palæontological history of the earth shows us the successive production of the different animal forms—first the fishes, then the amphibia, next the inferior mammals, and last the superior mammals.

Side by side with these two orders of evolution there is a third parallel with them: it is that which is found particularly expounded in the works of Cuvier, Goethe, Meckel, Johannes Müller, Gegenbaur, Huxley, and forms the subject of comparative anatomy. This science seeks to determine what is common to the forms of different species, and studies living beings from the point of view of the scale of perfection. In this respect also we find that fishes, amphibia, and the inferior mammals stand in the same relation to man as from the standpoint of embryonic evolution and of palæontology. Now, this triple parallelism of individual development, of palæontological development, and of systematic development, is completely explained by the theory of transformation, by the laws of heredity and adaptation, while no opponent of the theory of evolution has ever been able to account for it in a natural and philosophic manner. Haeckel concludes from this that we shall be compelled to admit Lamarck's theory of evolution, if we are not led to accept Darwin's theory of selection.

SOCIETIES AND ACADEMIES

London

Royal Society, Feb. 20.—"On the Anatomy of the Land Planarians of Ceylon." By H. N. Moseley, M.A., Exeter College, Oxford.

Two new species of Land Planarians from Ceylon are described as belonging to the genus *Bipalium* (Stimpson), *B. Ceres*, the other to that of *Rynchodemus*, *R. Thwaitesii.*

With regard to the habits of *Bipalium*, the most interesting facts noted are that these animals use a thread of their body-slime for suspension in air, as aquatic Planarians were observed to do for their suspension in water by Sir J. Dalyell, and the cellar-slug does for its suspension in air. The anatomy of the Planarians was studied by means of vertical and longitudinal sections from hardened specimens. The skin in *Bipalium* and *Rynchodemus* closely conforms to the Planarian type, but is more perfectly differentiated histologically than in aquatic species, and approaches that of the leech in the distribution, colour, and structure of its pigment, and especially in the arrangement of the glandular system. The superficial and deep glandular systems of the leech are both here represented. In *B. Ceres* peculiar glandular structures exist, which may foreshadow the segmental organs of Annelids, it being remembered that these segmental organs are solid in an early stage of development. Rod-like bodies are present in abundance, though, singularly enough, Max Schultze failed to find any in *Geoplana*. These rod-like bodies are probably homologous with the nail-like bodies of Nemertines; and it is possible that the setæ of Annelids are modifications of them.

The muscular arrangement in *Bipalium*, which is very complex, throws great light on the homologies between the muscular layers of *Turbellaria* and those of other Vermes. In *Bipalium* there is an external circular muscular coat, which even presents the same imbricated structure which is found in it in leeches and other worms. In *Dendrocœlum lacteum* there is also an external circular coat. In cases where a distinct external circular muscular coat is absent, it is represented by a thick membrane, which is very probably contractile. All Turbellarians are built on the same essential type, as regards muscular arrangement, as are other worms. The general muscular arrangements in the bodies of the *Bipalium* and *Rynchodemus* have become much modified from those of flat Planarians by the pinching together and condensation of the body, but they are nevertheless referable to the same type.

The digestive tract consists of three tubes, one anterior, two posterior, as in other Planarians, and as in the embryo leech before the formation of the anus. Characteristic of land Planarians, and consequent on the condensation of the body, is the absence of all diverticulæ from the inner aspects of the two posterior digestive tubes. The close approximation of the intestinal diverticula in *Bipalium* and *Rhynchodemus*, and the reduction of the intervening tissue to a mere membranous septum, is very striking, and seems to foreshadow the condition of things in Annelids. The great difference in the form of the mouth in *Rhynchodemus* and *Bipalium* is also remarkable, considering the many points in which these forms are closely allied.

A pair of large water-vascular trunks, or, as they are here termed, primitive vascular trunks, are conspicuous objects in transverse sections of the bodies of *Bipalium* and *Rhynchodemus*. A peculiar network of connective tissue is characteristic of these vascular canals on section, and is shown to present exactly similar features in *Leptoplana tremellaris*, *Dendrocœlum lacteum*, and *Bothriocephalus latus*. The close agreement in the relative position of the oviducts to the vascular canals in *Dendrocœlum* and our land Planarians is very remarkable. The nerves and ganglia of Planarians lie within the primitive vascular system, as do the corresponding structures within the primitive body-cavity of the leech.

A small marine Planarian was found to contain hæmoglobin. In *Bipalium* there are a series of separate testes disposed in pairs, as in the leech. In *Rhynchodemus* the testicular cavities

are more closely packed, and follow no such definite arrangement. The ovaries are simple sacs in both *Bipalium* and *Rhynchodemus*, and are placed very far forwards in the head, a long distance from the uterus. In *Bipalium*, short branches given off from the posterior positions of the oviduct are the rudiments of a ramified ovary, such as exists in *Dendrocœlum lacteum*. The organs described as nervous ganglia by Blanchard in *Polycladus* are almost certainly its testes and ovaries, and therefore the arrangement of these bodies in *Polycladus* is the same as that in *Bipalium*.

The nervous system is ill defined, but appears to consist of a network of fibres without ganglion-cells, which lies within the primitive vascular canals.

Numerous eye-spots are presented in *Bipalium*, most of them being grouped in certain regions in the head, but some few being found all over the upper surface of the body, even down to the tail. In *Rhynchodemus* two eyes only are present. All gradations would appear to exist between the simple unicellular eye-spot of *Bipalium* and the more complex eye of *Leptoplana* or *Geodesmus*, where the lens is split up into a series of rod-like bodies, forming apparently a stage towards the compound eyes of Articulata.

In considering the general anatomy of *Bipalium*, it is impossible to help being struck by the many points of resemblance between this animal and a leech. Mr. Herbert Spencer has, in his "Principles of Biology," placed a gulf between Planarians and leeches by denoting the former as secondary, the latter as tertiary aggregates, so called because consisting of a series of secondary aggregates formed one behind the other by a process of budding. It is obvious, however, that a single leech is directly comparable to a single *Bipalium*. The successive pairs of testes, the position of the intromittent generative organs, the septa of the digestive tract, and most of all, the pair of posterior cæca, are evidently homologous in the two animals. Further, were leeches really tertiary aggregates, the fact would surely come out in their development, or at least some indication of the mode of their genesis would survive in the development of some annelid. Such, however, is not the case. The young worm or leech is at first unsegmented, like a Planarian, and the traces of segmentation appear subsequently in it, just as do the protovertebræ in vertebrates which Mr. Spencer calls secondary aggregates. If Mr. Spencer's hypothesis was correct, we should expect to find at least some Annelid developing its segments in the egg as a series of buds. It is not, of course, here meant to be concluded that Annelids are not sometimes in a condition of tertiary aggregation, as *Nais* certainly is when in a budding condition, but that ordinarily they are secondary and not tertiary aggregates, and if so, then so also are Arthropoda.

"On a new Locality of Amblygonite, and on Montebrasite, a new hydrated Aluminium and Lithium Phosphate." By M. Des Cloizeaux.

Geological Society, Feb. 5, Warington W. Smyth, F.R.S., vice-president, in the chair. The following communication was read:—"On the Oolites of Northamptonshire.—Part II." By Samuel Sharp, F.G.S. In the first part of this memoir the succession of beds in the neighbourhood of Northampton was shown to be as follows:—

	Clay White Limestone Clay with Ferruginous Band... ("Upper Estuarine")	Great Oolite.
	Line of Unconformity.	
Northampton Sand	Sand with Plant Bed ("Lower Estuarine") Variable Beds Ironstone Beds	Inferior Oolite.
	Upper Lias Clay.	

The Great Oolite limestone of this section has been confounded, even up to the present time, with a limestone (frequently Oolitic) which occurs between Kettering and Stamford, is prevalent about the latter town, extends through Rutland and Lincolnshire (where it attains a thickness exceeding 200 feet) and into Yorkshire, which limestone has been distinguished by Mr. Judd as the "Lincolnshire limestone." The object of the author was to show that these two limestones were distinct, and that while the former was of the Great Oolite period, the latter as certainly belonged to the Inferior Oolite; and in citing evidence in proof of this position upon stratigraphical and palæontological grounds, he gave a general account of the geology of the northern division of Northamptonshire, illustrating his description by the exhibition of numerous fossils gathered from the various beds and localities referred to. Between Northampton and Kettering, the Great Oolite limestone is the surface rock; and intersecting valleys upon that line, and the escarpment of the Ise valley, a mile east of Kettering, exhibit this sequence of beds:—

Great Oolite	Limestone.	
,, ,,	Upper Estuarine Clays.	
Inferior Oolite	Lower Estuarine Beds	Northampton Sand.
,, ,,	Ferruginous Beds	
Upper Lias	Clay.	

And this section, with the successive superaddition of Great Oolite, Clay, Cornbrash, Kelloway Rock, and Oxford Clay, is continued due east across the country to the Valley of the Nene, and on into Huntingdonshire. Upon the same Ise escarpment, about a mile north-east of Kettering, the thin end of the wedge of the Lincolnshire limestone is seen to come in; and this sequence, for the first time, is presented:—

Great Oolite	Limestone.	
,, ,,	Upper Estuarine Clays.	
Inferior Oolite	LINCOLNSHIRE LIMESTONE (very thin).	
,, ,,	Lower Estuarine Beds	Northampton Sand.
,, ,,	Ferruginous Beds	
Upper Lias	Clay.	

The same sequence, with the occasional superaddition of the Great Oolite Clay, was shown to be repeated upon the western escarpment of the Ise, at Glendon, Barford Bridge, near Rockingham at Weekly, and at Geddington (the Lincolnshire limestone increasing in thickness at every advance), and to occur over and over again upon innumerable escarpments in the counties of Northampton, Rutland, Lincoln, and York, offering unmistakeable and incontrovertible evidence of the true stratigraphical position of the Lincolnshire limestone.

February 21.—Annual General Meeting. His Grace the Duke of Argyll, K.T., F.R.S., president, in the chair. The Secretary read the Reports of the Council, and of the Library and Museum Committee. The general position of the Society was described as satisfactory, and the number of Fellows is said to have essentially increased.

In presenting the Wollaston Gold Medal to Sir Philip de Malpas Grey-Egerton, Bart. F.R.S., F.G.S., the president spoke as follows:—"Sir Philip Egerton,—I consider myself fortunate in being the organ of the Geological Society in presenting you with the Wollaston Medal, which has been awarded to you by the Council for the present year. The eminent services which you have rendered to geology during a period now extending over forty years have long been familiar to scientific men, and have given you more than a European reputation. These services have been so great and so universally recognised, that the only difficulty I now have is not in assigning grounds for the vote which I have the pleasure of announcing, but in explaining why it has been so long delayed. That delay has been occasioned, I believe, solely by the fact that you have yourself been so long an honoured member of the Council whose duty it is to consider the claims of geologists for the honours of this Society; and whatever influence you have had in that body has doubtless been exerted in favour of others to the exclusion of yourself. It is at least some compensation for the loss which the Council sustains in your absence that it is now able to accord a recognition which has long been due. The many papers which you have contributed to this Society from 1833 down to the present time are a sufficient indication of the wide range of your observations. But the special attention you have bestowed, and the light you have thrown on the structure and affinities of fossil fishes and reptiles, have been of the highest value, and have formed in the aggregate a most important contribution to our knowledge of the history of organic life. I have the highest pleasure in now handing to you the Wollaston Medal."

Sir Philip Egerton, in reply, said:—"My Lord President, I know not whether it is owing to the poverty of the English language or to my unskilfulness in use of it, but I am quite at a loss for words adequate to express my appreciation of the great and unexpected honour conferred upon me by the award of the Wollaston Medal, and for appropriate terms to convey to your Grace my acknowledgments of the kind, but too flattering terms you have used in communicating the decision of the Council; and my embarrassment is increased by the consciousness that, in comparison with those illustrious names which already adorn the Wollaston roll, I am quite unworthy

of this great distinction. I cannot presume to think that the humble contributions I have been enabled to make to geological knowledge (and indeed to but a limited branch of it) can have been weighed in the balance against the labours of many others on both sides of the Atlantic, whose lives have been devoted to geological research, but who have not yet attained the distinction awarded to me to-day. In comparison with these my claims are quite insignificant. I must therefore look elsewhere to discern the motive which has influenced the Council in selecting my name on the present occasion in preference to others whose scientific claims are far greater than my own, and I think I am right in assigning it to a desire on their part to recognise, encourage, and occasionally reward the labours of those who although their lot in life has been cast in a sphere entailing many paramount duties which ought not to be neglected, nevertheless devote their leisure time to the promotion of scientific research rather than waste it in frivolous and unproductive amusements. In this sense I interpret the mind of the Council in awarding me this medal, and in this sense, as also as a stimulus and incentive to persevere in the cause of that science in which I take so deep an interest, and from the study of which I have derived so much intellectual enjoyment, I can, without arrogance, most gratefully accept it. May I be permitted to add, that if anything could enhance the feelings of gratification I experience in receiving this, the *blue ribbon* of geology, it is that it is presented by a President who, although occupying the highest social rank, and called by our gracious Sovereign to fill the highest offices of State, entailing most onerous duties and grave responsibilities, has nevertheless devoted himself to the study of scientific problems, and has inscribed for himself a name on the tablets of scientific literature, indelible so long as the Reign of Law shall continue to exist."

The President then presented the balance of the proceeds of the Wollaston Donation-Fund to Mr. J. W. Judd, F.G.S., and addressed him as follows:—"Mr. Judd,—I have much pleasure in delivering to you the award of the Council of this Society in recognition of your valuable researches in the Neocomian and Jurassic rocks of England, researches which you are now extending with such marked success to the Secondary and Palæozoic rocks of Scotland. I rejoice to know that you are to carry to an investigation of the West coast of Scotland the experience and knowledge you have shown in your recent account of the Secondary rocks of the East coast. The scattered and broken remains of the Oolites in the Hebrides constitute a most interesting field of investigation; and a detailed examination of them conducted by you cannot fail to cast important light on many geological problems of the highest interest to our science."

Mr. Judd made the following reply:—"My Lord President,—The recollection of an occasion like the present may well be cherished by a student of science as an incentive to exertion second only to the enthusiasm of research itself. Having learned to look to this Society, and never in vain, for the encouragement of sympathy and the guidance of criticism, it is with especial gratification that I receive this mark of confidence at the hands of my teachers and fellow-workers. When I think of the origin and traditions of this bequest—the objects contemplated by its illustrious founder, the distinguished geologists who have been its former recipients, and the important researches to which it has been made contributory—I am deeply impressed by the trust which you have reposed in me. It is my hope that by earnest labour I may be able to testify that my feelings of gratitude are not evanescent, nor my sense of responsibility light, in connection with the great honour which you have this day done me."

The President then presented the Murchison Medal to Mr. William Davies, of the British Museum, and addressed him as follows:—"Mr. Davies,—I have much pleasure in delivering to you the Murchison Medal, which has been awarded to you by the Council of this Society in recognition of the services you have rendered to Palæontology, in the skill and knowledge you have displayed in the reconstruction of extinct forms of life. I have the more pleasure in giving this medal, as I believe you will have the greater pleasure in receiving it, from the fact that it is the first award made under and in fulfilment of the will of the great geologist and excellent man whose loss we have all had so lately to deplore. I trust it may long serve to stimulate others to such services as you have rendered, and which have appeared to the Council of this Society to make you a worthy recipient of the First Murchison Medal."

Mr. Davies in reply said:—"My Lord Duke, I desire to return my most sincere thanks to your Grace as President, and to the Council of this Society, for the honour they have conferred upon me in awarding me the Murchison medal. It is extremely gratifying to find that the humble services I have rendered to Palæontological science have been so kindly appreciated and deemed worthy of this high recognition. The pleasure is greatly enhanced by the fact that I have never considered my scientific work of sufficient importance to deserve any recognition—the acquisition of scientific knowledge and the happiness of communicating it to others having, in my own case, been its own reward. I shall now feel it to be my duty as well as my ambition to render myself more worthy of the distinction you have this day conferred upon me—one which has also an especial significance to a servant of that great National Institution for which Sir Roderick Murchison so long and beneficially acted as a Trustee."

The President then delivered to Prof. Ansted, F.R.S., For. Sec., for transmission to Prof. Oswald Heer, of Zürich, the balance of the Murchison Fund, and spoke as follows:—"Mr. Secretary,—The labours of Prof. Heer in fossil botany and entomology have this year been recognised by this Council in the vote of the Murchison Fund. No branch of Palæontology requires more minute research, more careful comparison, more circumspect conclusions—and there are none, I may add, which, when so conducted, are richer in suggestions on the history of geological change. The fragmentary character which generally belongs to terrestrial and especially to botanical remains, places the study of them under special difficulties, difficulties which have been met with special skill by Prof. Heer. The remains of the Miocene flora are connected with some of the most perplexing problems of our science, and the light which has been thrown upon them by Prof. Heer more than deserves the recognition which I have now the pleasure of delivering into your hands for trnnsmission to that distinguished man. This is the second mark of recognition which this Society has given to Prof. Heer, the Wollaston Donation Fund having been voted to him in 1862."

Prof. Ansted having suggested that Sir Charles Lyell, as a particular friend of Prof. Heer's, might very appropriately speak in his name, Sir Charles Lyell in reply referred briefly to the nature of Prof. Heer's work, and said that he was sure that gentleman would appreciate highly this renewed expression of the interest taken by the Geological Society in his pursuits. Sir Charles Lyell remarked further, that he was particularly gratified that this award had been made at the present time, as Prof. Heer was well advanced in years and in an exceedingly infirm state of health, so that perhaps another opportunity of showing him respect and sympathy might not occur.

The President then read his Anniversary Address, in which he discussed the phenomena of denudation, referring especially to the influence of subterranean and other movements of the crust of the earth upon the denudation of its surface, and disputing the greatness of the denuding effects of glacial action. The Address was prefaced by biographical notices of deceased Fellows, including Prof. Sedgwick, Dr. Kelaart, Mr. Augustus Smith, Mr. N. Beardmore, and Prof. Pictet.—The Ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President: the Duke of Argyll, K.T., F.R.S.; Vice-Presidents: Prof. P. Martin Duncan, F.R.S.; R. A. C. Godwin-Austen, F.R.S.; Joseph Prestwich, F.R.S.; Prof. A. C. Ramsay, LL.D., F.R.S. Secretaries: John Evans, F.R.S.; David Forbes, F.R.S. Foreign Secretary: Warington W. Smyth, F.R.S. Treasurer: J. Gwyn Jeffreys, F.R.S. Council: Prof. D. T. Ansted, F.R.S.; the Duke of Argyll; W. Carruthers, F.R.S.; Prof. P. M. Duncan, F.R.S.; Sir. P. de M. G. Egerton, Bart., M.P., F.R.S.; R. Etheridge, F.R.S.; J. Evans, F.R.S.; J. Wickham Flower; D. Forbes, F.R.S.; Capt. Douglas Galton C.B., F.R.S.; R. A. C. Godwin-Austen, F.R.S.; J. Whitaker Hulke, F.R.S.; J. Gwyn Jeffreys, F.R.S.; Sir Charles Lyell, Bart., F.R.S.; C. J. A. Meyer; J. Carrick Moore, F.R.S.; J. Prestwich, F.R.S.; Prof. A. C. Ramsay, F.R.S.; R. H. Scott, F.R.S.; W. W. Smyth, F.R.S.; Prof. J. Tennant, F.C.S.; W. Whitaker; Rev. T. Wiltshire, M.A., F.L.S.

Meteorological Society, Feb. 19.—Dr. J. W. Tripe, president, in the chair. The following papers were read:—"A description of an electrical self-registering Anemometer and rain-gauge," by the Rev. F. W. Stow, M.A. The general principle on which the registering apparatus is constructed is

that of the Morse telegraph instrument as worked in America. The tape is drawn by a clock at the uniform rate of 6 inches per hour. As it passes over a grooved brass roller, holes are punched in it by a sharp steel point, drawn down by an electro-magnet whenever the electric circuit is completed, and drawn back by a spiral spring when the contact is broken. There are two grooves in the roller and two electro-magnets, one of which is worked by the anemometer, and the other by the rain-gauge. Thus, when both magnets are in operation, two parallel rows of holes are punched in the tape.—" On the Madras Cyclone of May 2, 1871," by Captain H. Toynbee, F.R.A.S. After giving extracts from several logs containing data taken during the time of the hurricane, and observations taken at the Madras Observatory; the author says it seems fair to conclude that the centre of this cyclone passed to the W. and probably to the N.W. between the parallels of 10° and 13° N.; that its route was probably much interfered with by the high land to the W. and S.W. of Madras; but that it caused very disturbed weather on the west coast of India. The paper concludes with some practical suggestions as to how ships might more safely ride out a gale.—"On the character of the storm of August 21 and 23, 1868, over the British Isles," by Captain T. O. Watson.

Paris

Academy of Sciences, Feb. 17.—M. de Quatrefages, president, in the chair. A decree of the President of the Republic authorising the election of M. Janssen to the Academy was read, and M. Janssen admitted. M. Faye read the termination of his answer to Fathers Secchi and Tacchini; it was devoted to the refutation of Secchi's statement that spots were solar eruptions and the proof that they were down-rushes caused by cyclones.—M. A. Trecul read a paper on the carpellary theory as regards *Martynia fragrans*.—M. A. de Caligny contributed a further paper on hydraulic engineering, &c.—Colonel H. Levret sent a note on the determination of geographical position on any elipsoid, and M. Boutin a note on the presence of nitre in *Amarantus Blitum*; the dried plant contains 11·68 parts per cent. by weight of potassic nitrate.—M. T. Tissandier presented a description of some meteorological observations made in a balloon.—M. L. Hugo sent a note on two antique dodecahedra in the Louvre, and M. Brachet two microscope lenses made of spinelle ruby; he believes that these will act better than the portion of the object-glass which is usually made of crown glass. A letter from P. Tacchini with a drawing of the remarkable appearance of Jupiter during January was received.—M. J. Bourget sent a paper on the mathematical theory of Pinaud's experiments on the sounds produced by heated tubes.—M. Wurtz presented a note from Dr. L. C. de Coppet on the recent communications of MM. Gernez and Vander Mensbrugghe on super-saturated solutions.—M. Bussy commuuicated a note from M. Lefranc on atractylic acid; this acid occurs in *Atractylis gummifera* L.—MM. Schützenberger and Risler sent a paper on the oxidising power of blood.—The eighth note of M. P. Bert on experimental researches on the effect of changes of barometric pressure on life, was received.—M. Laboulbène communicated a note on the cause of the elevation of central temperature in cases of acute pleurisy, &c.—M. E. Rivière sent a note on the pre-historic station of Cape Roux.—From M. Champouillon a note on certain imperfections in the official report on recruiting in France was received.—M. Guerin sent a note on silkworm disease; he finds that both healthy and unhealthy moths lay sound eggs.

Feb. 24.—M. de Quatrefages, president, in the chair.—M. Pasteur read a note on M. Cornalia's report on silkworm cultivation. M. Pasteur believes that his system of preserving the healthy eggs will produce good results.—M. Dumas reported on Mr. Fayrer's book on Indian poison snakes.—M. J. Raulin presented a paper on the silkworm disease, and M. Hugo a note on a necklace of polyhedric beads in the Louvre. M. Ed. Weyer a note on left-handed curves of the sixth order. M. de Rebaucour on the cyclic systems, MM. Troost and Hautefeuille on the "solution" of gases in cast and wrought iron and in steel. The authors believe that the gases given off in the "boiling" of iron are due to decompositions in the iron itself.—M. Ch. Violette sent a note on the compound of sugar wlth potassic chloride, and M. Grimaux one on the solidifying points of solutions of acetic anhydride in water.—M. Bidaud sent a note on the flame reaction of boric anhydride. He finds it to be excessively delicate, with a coal-gas bunsen flame.—M. L. Ranvier sent a paper on the regeneration of cut nerves.—MM. D. Tommasi and G. Quesneville on the action of zinc on acetylic chloride; M. G. Perry, notes on the third ray in triple refracting crystals and on the variablity of the co-efficient of elasticity and dispersion.

DIARY

THURSDAY, March 6.

Royal Society, at 8.30.—On the Vapour Density of Potassium: J. Dewar and W. Dittmarr.—On New Sources of Ethyl and Methyl Aniline: J. Spiller.
Society of Antiquaries, at 8.30.—On the Troad: Sir John Lubbock.
Linnean Society, at 8.—On the Perigynium of Carex: G. Bentham.
Chemical Society, at 8.—On the Action of Hydrochloric Acid on Codeine: Dr. C. R. A. Wright.—New Process of Mercury Estimation, with some Observations on Mercury Salts: P. Hannay.—On a Method of Estimating Nitric Acid: T. E. Thorpe.—Note on the Action of Acetates upon Solutions of Plumbic Salts, with Remarks on the Solubility of Plumbic Chloride: F. Field.
Royal Institution, at 3.—Forces and Motions of the Body: Prof. Rutherford.

FRIDAY, March 7.

Royal Institution, at 3.—On the Temperature of the Sun and the Work of Sunlight: James Dewar.
Geologists' Association, at 8.—On the Geology of Brighton: James Howell.—On some Fossils from the Margate Chalk: W. Wetherell.
Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.

SATURDAY, March 8.

Royal Institution, at 3.—On the Philosophy of the Pure Sciences: Prof. W. K. Clifford.

SUNDAY, March 9.

Sunday Lecture Society, at 4.—The Education of Women: Mrs. Fawcett.

MONDAY, March 10.

Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.
London Institution, at 4.—Physical Geography: Prof. Duncan.
Royal Geographical Society, at 8.30.—Notes of a Journey in Southern Formosa: J. Thomson.
Cantor Lectures, at 8.—On the Energy of Light, with especial reference to the Measurement and Utilisation of it: Rev. Arthur Rigg.

TUESDAY, March 11.

Photographic Society, at 8.—On the Development of Negatives and Transparencies: Col. Stuart Wortley.—On the Photographic Operations for observing the coming Transit of Venus: Lord Lindsay.
Royal Institution, at 3.—Forces and Motions of the Body: Prof. Rutherford.

WEDNESDAY, March 12.

Society of Arts, at 8.—On Signalling at Sea, with special reference to Signals of Distress: Capt. Colomb.
Geological Society, at 8.—On the Solfatara, and some Sulphur-deposits at Kalamaki, near Corinth: Prof. Ansted.—On the Origin of Clay-ironstone: J. Lucas.—Note in vindication of Leptophlæum rhombicum and Lepidodendron gaspianum: Principal Dawson.—Synopsis of the younger formations of New Zealand: Captain F. W. Hutton.
Archæological Association, at 8.
London Institution, at 7.—Fresco and Siliceous Painting: Prof. Barff.
Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.

BOOKS RECEIVED

English.—The Student's Manual of Comparative Anatomy and Guide to Dissection, Part 1, Mammalia: G. H. Morrell, M.A.—The Romance of Astronomy: R. K. Miller (Macmillan).—Colymbia (Trübner).—A Course of Qualitative Chemical Analysis: W. G. Valentin (Churchill).—Exalted States of the Nervous System. 3rd Edition: R. H. Collyer (Renshaw).—The Story of the Earth and Man: J. W. Dawson (Hodder and Stoughton).

HERBERT SPENCER'S PSYCHOLOGY*

The Principles of Psychology. By Herbert Spencer. Second edition. (Williams and Norgate.)

II.

TO the healthy scientific mind the fine-spun arguments and the wonderful logical achievements of metaphysicians are at once so bewildering and so distasteful that men of science can scarcely be got to listen even to those who would undertake to show that the arguments are but cobwebs, the logic but jingle, and the seeming profundity little more than a jumble of incongruous ideas shrouded in a mist of words. Hence, it is hardly known that one of the two living thinkers who in philosophy stand head and shoulders above all their contemporaries, has put forth all his strength in a grand effort to demonstrate the baselessness, the inconsistency, the unreality of all anti-realistic metaphysics. The disciples of Berkeley and Hume, skilful in argument, and generally armed with a psychology superior to that of their antagonists, have hitherto gained easy victories over the hosts of theologians, who, confident in the truth of their cause, have stood forward, as one might say, unarmed and with naked breast, to fight for the reality of mind and matter. So easily and so invariably have the sceptics and idealists remained masters of the field against all-comers that they have agreed among themselves to regard realism as an exploded superstition "altogether unworthy of the name of philosophy" (Prof. Bain). But the end is not yet. They will have once more to look to their weapons. In Mr. Spencer realism has for the first time found a champion that can do it justice. Nothing behind the acutest idealist in subtlety and force of intellect, he brings to bear on the great metaphysical question of the reality of an external world a psychology as much superior to that of the idealists, as their mental science was superior to that of the divines they so easily vanquished.

Of course we shall not attempt to sketch the argument that occupies nineteen chapters of Mr. Spencer's volume; which has for its groundwork his whole system of psychology, and on the issue of which he considers that his entire philosophy is at stake; for, in his own words, ' should the idealist be right, the doctrine of evolution is a dream." It may, however, not be altogether profitless to dip into this elaborate argument at one or two places. "The argument of the Realist," says Mr. Spencer, "habitually fails from not having as a fulcrum some universally-admitted truth which the Idealist also has to admit." This necessary fulcrum, he alleges, is to be found in the Universal Postulate, which is, that we must accept as true that of which the negation cannot be represented in thought. But, it would almost seem no more easy to obtain universal assent to the doctrine, that the ultimate appeal must be to the inconceivableness of the negation of a proposition, than to establish the truth of realism by argument without the aid of such a fulcrum. At least, Mr. Mill and Mr. Spencer have been battling over this question for twenty years, without coming much nearer agreement than at the beginning. But though they may have done little towards their mutual instruction, many students of philosophy must have profited greatly from what they agree in describing as their "amicable controversy." And in venturing briefly to review the discussion, our justification must be that we do so as a disciple, who studies with reverence the works of both these imperial intellects. We shall first endeavour to outline in as few words as possible what appears to us an important part of Mr. Spencer's argument, leaving his full meaning to become apparent when we proceed to notice some of Mr. Mill's strictures thereon. Propositions, says Mr. Spencer, "are the ultimate components of knowledge. The simplest intuition equally with the most complex rational judgment, has the same fundamental structure: it is the tacit or overt assertion that something is or is not of a certain nature—belongs or does not belong to a certain class—has or has not a certain attribute." "Propositions, then, constitute the common denomination to which all systems of belief, simple or complex, have to be reduced before we can scientifically test them." But propositions are of many kinds; some are relatively simple, some are highly complex. "There are some propositions which tacitly assert little more than they avowedly assert; while there are other propositions in which what is tacitly asserted immensely exceeds in amount what is avowedly asserted." Accordingly, to "compare conclusions with scientific rigour, we must not only resolve arguments into their constituent propositions, but must resolve each complex proposition into the simple propositions composing it." When intelligence is thus resolved into its simplest elements, it is found that there are cognitions of which the terms cannot be separated. Such cognitions we necessarily accept. To ascertain that the predicate of a cognition invariably exists along with its subject, all we can do is to make a deliberate and persistent effort to conceive the negation of the proposition, and having done this, "to assert the inconceivableness of its negation, is at the same time to assert the psychological necessity we are under of thinking it, and to give our logical justification for holding it to be unquestionable." Further, as it is only by the aid of cognitions of this class, and for the trustworthiness of which no higher warrant can be given, that propositions are linked together so as to form what we call proof or disproof, since "logic is simply a systematisation of the process by which we indirectly obtain this warrant for beliefs that do not directly possess it," it must follow that an attempt to invalidate a cognition of this class by a process of reasoning must somewhat resemble the mechanical absurdity of trying to lift the chair on which one sits. Now, the belief that a universe exists apart from and independently of our states of consciousness, is, according to Mr. Spencer, a cognition possessing this quality of highest certainty. When a man looks at a book without speculating, "he feels that the sole content of his consciousness is the book considered as an external reality, . . . he feels that do what he will he cannot reverse this act; . . . while he continues looking at the book, his belief in it as an external reality possesses the highest validity. It has the direct guarantee of the Universal Postulate."

Against this Mr. Mill has argued that the proposed warrant of the truth of propositions cannot be accepted, if for no other reason, because we know as a matter of

* Continued from p. 300.

history that some propositions the negation of which was at one time inconceivable are now known to be false. His examples are—that in sunrise and sunset, it is the sun that moves; that gravitation cannot act through space absolutely void; and that there cannot exist antipodes—men sticking on by their feet to the under side of the earth. For the truth of each of these propositions Mr. Mill thinks that our forefathers had the warrant of what Mr. Spencer calls the Universal Postulate. "To this criticism of Mr. Mill," says Mr. Spencer, referring to the first and last of these propositions, "my reply is that the propositions erroneously accepted because they seemed to withstand the test, were complex propositions to which the test is inapplicable." Unfortunately, in his anxiety to "leave no possibility of misapprehension," Mr. Spencer mentioned, among other things, that we cannot by simple comparison of two states of consciousness know that the square of the hypothenuse of a right-angled triangle equals the sum of the squares of the other two sides. The strange result has been that Mr. Mill has, we cannot help thinking, fallen into a complete misapprehension of his meaning. In the eighth edition of his Logic, Mr. Mill has had the opportunity of replying to Mr. Spencer's argument as it stands in the volume before us. He there says: "It is but just to give Mr. Spencer's doctrine the benefit of the limitation he claims—viz. that it is only applicable to propositions which are assented to on simple inspection, without any intervening media of proof. . . . But in all the three cases which I have just cited (those mentioned), the inconceivability seems to be apprehended directly; no train of argument is needed, as in the case of the square of the hypothenuse, to obtain the verdict of consciousness on the point." We submit that the quality of being "assented to on simple inspection, without any intervening media of proof" is not the distinguishing characteristic of what Mr. Spencer calls a simple proposition. The propositions that can be properly brought to the test of the inconceivableness of their negation are not such as are assented to on simple inspection, but such as "are not further decomposable." Until this misconception on the part of Mr. Mill furnished conclusive evidence to the contrary, we were inclined to think that here, as elsewhere, Mr. Spencer had been needlessly tedious in stating and re-stating, illustrating and re-illustrating his meaning. That after all Mr. Mill should have so completely missed the true nature of his distinction of propositions into simple and complex is very remarkable. Had not Mr. Spencer declared that the propositions in dispute were examples of what he considered complex propositions? There is no intervening media of proof when we automatically interpret our sensations of sight into such a cognition as —"There is an old man." Yet this is one of the propositions tediously analysed by Mr. Spencer, "to show distinctly the number of propositions included in an ordinary proposition which appears simple. Again, "On a cold winter's night a gas-light seen through the window of a cab, or a light in a shop looked at through a pane that has been much rubbed, is surrounded by a halo. Whoever examines will see that this halo is caused by scratches on the glass, the curves of which are arcs of circles having the light for their centre. The proposition which expresses the result of his observation, and seems to assert no more than the result of his observation, is that on the part of the glass through which he looks the scratches produced by rubbing are arranged concentrically with the light." Included in this apparently simple proposition, however, is this other—"that there does not exist on the same spot scratches otherwise arranged, immeasurably exceeding in number the concentric scratches." The truth is that "the scratches on any part of the glass have no concentric arrangement at all, but run in countless directions with multitudinous curvatures." The propositions in question obviously belong to this class. In the assertion, the sun moves from east to west, there is included the other proposition—the earth does not revolve on its axis from west to east. We scarcely think that Mr. Mill will assert that any human being ever found it impossible to conceive, in Mr. Spencer's sense, that a sphere should so revolve. Thus far, then, we are bound to say that Mr. Spencer's argument remains intact.

With regard to gravitation we cannot do better than quote the note in which Mr. Mill replies to Mr. Spencer on this point:—

"In one of the three cases, Mr. Spencer, to my no small surprise, thinks that the belief of mankind 'cannot be rightly said to have undergone' the change I allege. Mr. Spencer still thinks we are unable to conceive gravitation acting through empty space. 'If an astronomer vowed that he could conceive gravitative force as exercised through space absolutely void, my private opinion would be that he mistook the nature of conception. Conception implies representation. Here the elements of the representation are the two bodies and an agency by which either effects the other. To conceive this agency is to represent it in some terms derived from our experiences—that is from our sensation. As this agency gives us no sensations, we are obliged (if we try to conceive it) to use symbols idealised from our sensations—imponderable units forming a medium.' If Mr. Spencer means that the action of gravitation gives us no sensations, the assertion is one than which I have not seen, in the writings of philosophers, many more startling. What other sensation do we need than the sensation of one body moving towards another? 'The elements of the representation' are not two bodies and an 'agency,' but two bodies and an effect; viz. the fact of their approaching one another. If we are able to conceive a vacuum, is there any difficulty in conceiving a body falling to the earth through it?"

We are compelled to say that Mr. Mill could not have been much more surprised at Mr. Spencer's statement than we are at his answer. What was it that Newton could not conceive, but which, Mr. Mill says, we have no difficulty in conceiving? Was Newton incapable of forming a mental representation of "one body moving towards another?"—an experience that in common with everybody else, he had hundreds of times every day of his life. No. To put it in plain rough language, he was unable to conceive how one body could move another without in some way pushing or pulling at it. Hence, when he tried to represent in thought the action of the sun upon the earth he found it necessary to imagine a medium—an unbroken line of physical connection between the two bodies. Have we got beyond Newton in this respect? or is it not rather, as Mr. Spencer says, that our scientific men have simply "given up attempting to conceive how gravitation results." Nay, are there not

at the present moment some indications that before long scientific men may return to this very problem?

Let us now advance a step. When it is found that we cannot conceive the negation of a proposition—that the subject and predicate cannot be separated in thought; "then, indeed," says Mr. Mill, "the inability to separate the two ideas proves their inseparable conjunction, here and now, in the mind which has failed in the attempt: but this inseparability in thought does not prove a corresponding inseparability in fact; nor even in the thoughts of other people, or of the same person in a possible future." No matter for the present, how we come by our cognitions, this is surely admitting what Mr. Spencer calls the psychological necessity of thinking the proposition. In the next place, we must confess that we have never been able intelligibly to translate into the language of idealism those anti-realistic arguments that appeal to "fact" and to the experiences of "other people." But, whatever may be meant by fact, and whatever may have a place in the minds of other people, it must for ever remain nothing to those in whose consciousness it can be neither presented nor represented. Our science of numbers is not likely to be disturbed because it can be written in words that, perhaps in some inaccessible corner of the universe, or in some mind of a different make from the human, twice two makes five. We have already examined the examples given by Mr. Mill of propositions that have, as he thinks, passed from the condition of being inconceivable to that of being both conceivable and believed, and therefore we do not think it necessary to discuss the probability of any really simple and inconceivable proposition becoming conceivable in the mind of the "same person in a possible future."

We must pass to the next step in the argument as sketched above. Does reasoning rest on the postulate? We cannot help thinking with regret that Mr. Mill has not felt it necessary to put forth his full strength on this point; and we are by no means sure that we have grasped his full meaning. His words are:—"To say that when I apprehend that A is B and that B is C, I cannot conceive that A is not C, is to my mind merely to say that I am compelled to believe that A is C. If to conceive be taken in its proper meaning, viz., to form a mental representation, I may be able to conceive A as not being C. After assenting with full understanding to the Copernican proof that it is the earth, and not the sun, that moves, I not only can conceive, or represent to myself, sunset as a motion of the sun, but almost everyone finds this conception of sunset easier to form than that which they nevertheless know to be the true one." This, as we understand it, seems open to the reply that, had sunset, considered as a motion of the sun, been inconceivable to begin with, no argument would have been needed to disprove it. Having followed the Copernican proof, we cease to believe that the sun moves, we remain, however, still able to conceive its doing so; for though we cannot help believing that of which we cannot conceive the negation, it does not follow that we are unable to conceive the negation of everything that argument has compelled us to believe. But, whether by following a sound argument we are or are not rendered incapable of conceiving the reverse of the conclusion, has, in reality, nothing to do with the question whether reasoning rests or does not rest on the postulate. To invalidate Mr. Spencer's argument by the method he has adopted, Mr. Mill would require to be able to represent in thought, not the sun moving through the heavens, in spite of the Copernican proof to the contrary but that at any step in the argument the conclusion need not follow from the premises. If he could do this he might still be convinced by argument, but we do not see how he must necessarily be so. Mr. Spencer's contention is that reasoning rests on the postulate, not because a valid argument makes the reverse of the conclusion inconceivable, but because the axioms of logic have no higher warrant.

Want of space forbids us entering further into the controversy. For the same reason we are unable to enter upon the inquiry whether we can properly be said to believe that of which we cannot form a mental representation. Mr. Spencer's opinion is that we cannot, and accordingly "that anti-realelistic beliefs have never been held at all. They are but ghosts of beliefs, haunting those mazes of verbal propositions in which metaphysicians habitually lose themselves. Berkeley was not an idealist; he never succeeded in expelling the consciousness of an external reality, as we saw when analysing his language and his reasonings. Hume did not in the least doubt the existence of matter or of mind; he simply persuaded himself that certain arguments ought to make him doubt. Nor was Kant a Kantist: that space and time are nothing more than subjective forms was with him, as it has been and will be with every other, a verbally-intelligible proposition, but a proposition that can never be rendered into thought, and can never therefore be believed."

DOUGLAS A. SPALDING

GEIKIE'S PRIMER OF PHYSICAL GEOGRAPHY

Physical Geography. By Prof. Geikie. Science Primer Series. (Macmillan.)

IT must not be supposed that this is the Physical Geography which we have been expecting from Prof. Geikie. It is a little book of 110 pages, truly a primer, and only makes us more eager to get a larger work.

The primer is written in a vivacious style; the style of a man really interested in what he is talking to his readers about; and in all respects suitably written for its purpose. It would be a little too patronising if it were intended for any but the very young, who like being taken into the confidence of the writer, and spoken to as young friends. It is to be hoped that a larger work may be equally vivacious and vigorous without this characteristic, which is, to repeat, not a fault in the primer, but would be a serious fault in the larger work intended for older boys and readers generally. It is a fault that pervades Kingsley's scientific books: it is a small annoyance at first, but finally "aggravates" one beyond all endurance. Moreover, the book is well illustrated with new, good, and unconventional woodcuts, and is thoroughly well-arranged and printed.

Now for its contents. After its introduction, which is in fact on "eyes and no eyes," we have the shape of the earth, day and night, the air, wind, vapour, dew, mist, rain, snow; the circulation of water on the land, springs, hard and soft water, atmospheric denudation (in shorter words than these), brooks, rivers, snow-fields, glaciers;

then the sea, stratification, coral; and lastly earthquakes and volcanoes.

Now this is just right. Physical Geography ought to contain the dynamics of geology, and not be a mere description of the physical condition of the globe. A description of the plateaus and primary mountain chains, and secondary mountain chains, and plains and river systems of all the countries in the world, and distribution of birds, beasts, and fishes, used to be what was called physical geography: and in it the dynamical element, all idea of change and progress was almost entirely left out. All this description constitutes geographical knowledge, but is of the nature of information pure and simple, and has absolutely no value in education except as an exercise in memory, and as a basis for reasoning, supposing that this reasoning is ever superposed. But what Prof. Geikie gives us is the very life and soul of geological science, observation on what the natural forces around us are doing, information as to what they are doing of the like kind elsewhere, and reasoning on the effect of these forces. It is a book which will at once rouse the curiosity of a child, and train it as far as it goes in sound scientific method.

It is admirably adapted to be a reading book in elementary schools, and it is much to be hoped that it will be largely used. But for this purpose a cheaper edition ought to be published. J. M. W.

OUR BOOK SHELF

Exalted States of the Nervous System. By R. H. Collyer, M.D. (H. Renshaw.)

It can only be with a feeling of regret that anyone can see so many pages, nearly 150, occupied with matter and arguments most of which had much better have been retained only among the oral traditions of the author's acquaintances, for by publishing them he lays himself open to the severe criticisms of a non-appreciating scientific public. That Dr. Collyer was among the first to propose and employ anæsthetics, we will not question, but he cannot expect to increase the number of his supporters by the publication of such a work as the above, in which his want of knowledge of the first principles of scientific method and physiological fact is rendered too clear. An instance or two will suffice to indicate the manner in which the subject is treated. Speaking of chloral, he says—"It is administered by the stomach. . . . It seems that the action is immediate on the brain, through the eighth pair of nerves." This is very different from the explanation of the discoverer of that substance, and quite contrary to any explanation of value that has been since proposed. The physiological dogma on which the author bases many of his arguments is that "the lungs at every respiration send vital electricity to the brain, which has been thus assimilated to subserve the purposes of life." In a newspaper account of the relative chances of the Oxford and Cambridge crews for 1871, the author finds sufficient to justify the following valuable generalisation:—"thus endurance *does not belong* to mere size." We think these quotations sufficient.

The Botanists' Pocket-book: containing in a tabulated form the chief characteristics of British plants. By W. R. Hayward. (Bell and Daldy, 1872.)

A book of modest pretensions, and not without its value. As a rule there is no class of scientific literature to be more carefully avoided than that which professes to compress the whole of the elements of a science into a small portable volume; nowhere is the master's hand more urgently required than in the compilation of text-books. Mr. Hayward we do not recollect to have met with before as a botanical writer; this little book, however, evidences great care in its preparation, and the author is careful not to claim for it too high a place. Its object is to "afford information to the tyro, and also to refresh the memory of the more advanced botanist who, by examining on the spot any doubtful plant, may be saved the trouble of carrying home specimens of little value; it is not intended as a book for the study, nor as a rival to the many excellent and complete manuals of our leading botanists; but to be accepted for what it is, viz., 'A Botanist's Pocket-book.'" This purpose it may well serve; occupying not much over 200 pages of thin paper in limp cloth binding, it will be no great burden to the pocket or knapsack, and may frequently be usefully resorted to by a young botanist on the tramp, leaving more careful study till he gets home. A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Perception in the Lower Animals

As several persons seem interested in Mr. Wallace's suggestion that animals find their way home by recognising the odour of the places which they have passed whilst shut up, you may perhaps think the following little fact worth giving. Many years ago I was on a mail-coach, and as soon as we came to a public-house, the coachman pulled up for the fraction of a second. He did so when we came to a second public-house, and I then asked him the reason. He pointed to the off-hand wheeler, and said that she had been long completely blind, and she would stop at every place on the road at which she had before stopped. He had found by experience that less time was wasted by pulling up his team than by trying to drive her past the place, for she was contented with a momentary stop. After this I watched her, and it was evident that she knew exactly, before the coachman began to pull up the other horses, every public-house on the road, for she had at some time stopped at all. I think there can be little doubt that this mare recognised all these houses by her sense of smell. With respect to cats, so many cases have been recorded of their returning from a considerable distance to their homes, after having been carried away shut up in baskets, that I can hardly disbelieve them, though these stories are disbelieved by some persons. Now, as far as I have observed, cats do not possess a very acute sense of smell, and they seem to discover their prey by eyesight and by hearing. This leads me to mention another trifling fact: I sent a riding-horse by railway from Kent *viâ* Yarmouth, to Freshwater Bay, in the Isle of Wight. On the first day that I rode eastward, my horse, when I turned to go home, was very unwilling to return towards his stable, and he several times turned round. This led me to make repeated trials, and every time that I slackened the reins, he turned sharply round and began to trot to the eastward by a little north, which was nearly in the direction of his home in Kent. I had ridden this horse daily for several years, and he had never before behaved in this manner. My impression was that he somehow knew the direction whence he had been brought. I should state that the last stage from Yarmouth to Freshwater is almost due south, and along this road he had been ridden by my groom; but he never once showed any wish to return in this direction. I had purchased this horse several years before from a gentleman in my own neighbourhood, who had possessed him for a considerable time. Nevertheless it is possible, though far from probable, that the horse may have been born in the Isle of Wight. Even if we grant to animals a sense of the points of the compass, of which there is no evidence, how can we account, for instance, for the turtles which formerly congregated in multitudes, only at one season of the year, on the shores of the Isle of Ascension, finding their way to that speck of land in the midst of the great Atlantic Ocean?

CHARLES DARWIN

The Sense of Smell in Animals

THE hypothesis put forward by Mr. Wallace in NATURE of the 20th ult., to explain the power possessed by some animals of

finding their way back to their homes after having been conveyed from them in such a way as to preclude the possibility of their seeing the road by which they travelled, contains, I think, the solution of a hitherto perplexing problem. To ascribe this power, as is usual, to instinct in the customary sense of the term, is to give what Mr. Bain calls "an illusory explanation of repeating the fact in different language," and it is manifestly impossible to ascribe it to instinct, as that term is understood in the evolution theory of mind. I am glad to see a psychologist like Prof. Robertson giving in his adhesion to Mr. Wallace's view. But while in the main accepting it, and arguing forcibly in its favour, Prof Robertson hesitates to affirm that it affords an explanation of the whole of the facts in question. Is this failure, if failure there be, inherent in the explanation itself, or does it lie in our imperfect knowledge of the facts to be explained? That there are difficulties cannot be denied. For example, it is difficult, to say the least, for the human mind to form the conception of a sense of smell, so acute, so objective, and furnishing sensations so strongly persistent in the ideal, as to enable an animal by its means alone, to retrace unerringly long and devious roads travelled over but once, and under circumstances rendering impossible the co-ordination of sights and smells habitual to the animal. In such cases smell must be a much closer second, if second at all, to sight, than touch is in man. No blindfolded man could perform a like feat by means of unaided touch, nor, do I think, could a blind man, though with the blind this sense becomes, by the cultivation it receives through a hard necessity, greatly more acute than it is in normal cases. But difficulties like these are such, I believe, only because of our very limited acquaintance with the psychology of the lower animals. One of the chief desiderata in mental science is, it seems to me, such a psychology, based upon principles generalised according to strict inductive methods, from a body of numerous, varied, well-authenticated, and scientifically made observations of the domestic and other animals. A work of this kind we have not, but, I believe, the lines upon which it should be constructed are already laid down in Mr. Spencer's truly great work, the "Principles of Psychology." When this branch of psychological science has been brought into something like parallelism with human psychology, difficulties, such as I have hinted at, will, I venture to say, be effectually removed, and Mr. Wallace's explanation will, as he claims for it, "cover all the well-authenticated cases of this kind."

In the extended scope claimed for this hypothesis by Prof. Robertson, viz., as explanatory of the nature of external perception in dogs, there appears to be a difficulty raised. The most refined and deep-penetrating psychological analysis, of both the empiristic and evolution schools, have Incontestably established that our mature visual presentations are but symbols of the earlier and really genetic presentations acquired through touch combined with muscular feeling. Granting, as seems undeniable, that smell in dogs holds, in many respects, a place analogous to that of touch in man, would the earliest and the genetic presentations of externality in these animals be those furnished by smell, with or without the aid of muscular feeling?

Before concluding my letter, I should like to offer a remark upon the supposed *experimentum crucis* of Mr. Wallace's hypothesis, suggested by Mr. Bennett. The smell of stale fish would undoubtedly interfere with and overpower ordinary smells in the human organ. But is it not an anthropomorphical fallacy to assume, as Mr. Bennett appears to do, that such would be the result in the case of a cat? From the almost purely subjective and comparatively undeveloped sense of smell possessed by man, there appears to me to be no conclusive argument to the highly objective and extremely acute sense of smell possessed by certain animals. We are not warranted from our own experience in inferring of a sense, quantitatively, if not qualitatively, so very different, that one powerful sensation must necessarily exclude fainter sensations of a like order. Normally, vivid sensations of a particular order do tend to exclude with more or less completeness fainter like sensations. But the animal, in the circumstances in which it is placed, is as Mr. Wallace shows, in an abnormal condition. Its attention is concentrated on the unfamiliar succession of smells it is encountering, and under such a stimulus these ordinarily fainter sensations may not unreasonably be supposed to become unwontedly vivid, and capable of powerfully affecting the animal's consciousness, despite the resistance of what under common circumstances would prove an effectual obstacle to their conscious presentation. A complete *experimentum crucis* would require that the animal shoul , during the whole journey, be entirely smell-muffled, and Mr. Bennett's expedient could not, I think, be relied upon to produce this effect.

Camberwell, March 3 W. H. Brewer

External Perception in Dogs

The following somewhat remarkable instance of a dog finding its way back was told me by the owner, who lived 20 or 25 miles up (and on the left bank of) the river Canumá, in Brazil; a small river just east of the river Madeira. He took the dog by boat down the river Canumá and up the Madeira to Borba, a small town on the right bank of the latter river; a distance of 70 or 80 miles round; and left the dog there. The dog ran away from Borba and made its way back to its former home on the river Canumá. More exactly, it was making its way back, for my informant being out in the wood some little way inland, and S.W. of his cottage, fell in with it. It was in bad condition, having been some weeks—the exact time could not be ascertained—in working its way back through the forest, and of course had lived by hunting. I cannot give with any exactness the distance overland from Borba: perhaps it is less than 25 miles; and in this respect the return is not remarkable. It seems to me that the dog during its journey by water must have had a constant perception of the bearing of its old home; and on the other hand that it made its way back not by any blind instinct but by trial and error and by recognition of the character of the forest. F. R. G. S.

Sight in Dogs

I think Mr. Kingsley rather underrates the exercise of the organs of vision by the dog when, in comparing it with the horse, he writes,—"The dog, who has smelt everything, but looked at very little." Now it is true that the dog does not look about him when on his travels, in the popular sense, by turning his head about, but close observation shows the eyeball in constant movement, taking in everything in front and on both sides, although, to all appearance, with his head close to the ground, his whole attention is concentrated on the reception of external impressions through his nose. This is particularly noticeable in the terrier, which, on meeting you, however intently he may seem to be engaged in smelling, gives a quick glance at your face without moving his head, or apparently lessening the attention he is paying to something else with his nose. Note, also, how quickly a dog going down wind sees another a long distance off.

The horse not only sees and smells acutely but also frequently touches any object with his upper lip.

In reference to the quotation from "Boswell's Life of Johnson," given by Mr. Nicoll, I may mention that it is well known to huntsmen that horses are very prone to kick if led near the hounds when a fox is being broken up, the explanation always given being that it is the smell of blood which irritates them.

Faringdon, March 9 J. Hopkins Walters

Selenium

Vitreous selenium may be considered a non-conductor of electricity. It is only when in a crystalline condition that it becomes a conductor.

A bar now in my possession, $2.25 \times .5 \times .05$ inches, tested with an electromotive force of $\frac{1}{10}$th of a Daniell's cell, gives a deflection of 140 divisions on the scale of an ordinary astatic mirror galvanometer. The same deflection produced under the same conditions through a known resistance, shows the resistance of the selenium to be 360,000 ohms. By the well-known Bridge system the resistance of the same plate of selenium is 359,500 ohms, the two different tests thus confirming each other.

I have to leave this evening for Valentia to report on the electrical condition of the Anglo-American Company's cable, or would write you more fully on the effect of light on the conductibility of selenium.

If selenium be exposed to the direct rays of the sun, it gradually becomes crystalline. May not the explanation of the phenomenon be found in this fact?

All the bars I have experimented upon have been supplied by Mr. H. Bassett, No. 215, Hampstead Road.

Brighton Aquarium

I ADDRESSED a letter some weeks ago to the chairman of the Brighton Aquarium Company, in which, amongst other matters, I suggested that a stand with a few microscopes exhibited therein, which had been offered by a London maker, would be a source of great additional attraction, without being any expense to the company.

I also suggested that it might very likely be the nucleus of a school of marine zoology, if for a separate subscription the directors could set aside a room to be used by students, who might form themselves into a kind of club, and work with their miscroscopes and tanks in quiet. The nearness to London of the Brighton Aquarium might, I remarked, prove the inducement to many non-residents to join; whilst a library, and a few demonstrations, would give increased means of gaining information.

I think, sir, that the importance of my suggestions warrants my requesting you to make them public, since other aquaria might also take the matter up, without damage to the Brighton Company, in the success of which I take the warmest interest.

General Travelling Notes

I BELIEVE F. G. S. P. would find some of the information he wishes, in a small pamphlet which is to be obtained at the Royal Geographical Society, 1, Savile Row, price 1*s*. There is also an excellent little work (very portable) which has been recently published by some Fellows of the Anthropological Institute for the use of travellers, which would be found useful; price 1*s*.

J. RAE

New Guinea

THE *Academy* for July 15, 1872, contains a note on New Guinea, from *Petermann's Mittheilungen* in which there are two slight mistakes. Perhaps you will allow me to correct them in your journal.

It is said, "The London Missionary Society founded a number of stations on the south-eastern peninsula" in 1871, and that these stations were "in charge of educated natives of the Tongan Archipelago."

The stations founded by the agents of the London Missionary Society in 1871 were not on the large island of New Guinea, but on the small islands of Erub, Tauan, and Saibai in Torres Straits. The Society's vessel has, however, sailed this year with a staff of English and Polynesian missionaries on board, who hope to be able to occupy stations on New Guinea itself.

The "educated natives" placed as pioneers in the first settlements are not "natives of the Tongan Archipelago," but of the Loyalty Islands near to New Caledonia, and they belong to the black Polynesian, or Papuan race. The Tongan Islands are entirely under the care of the Wesleyan Missionary Society.

The missionaries who touched at New Guinea in 1871 believe they saw people similar to the brown Polynesians as well as the black frizzly haired Papuans proper. Hence, evangelists from both races of Polynesians have been sent to New Guinea this year.

Samoa, Nov. 6, 1872

Flight of Projectiles

YOUR correspondent, "Robert Reid," asks for an impossibility. There is no impossibility in calculating the theoretical deflection in the flight of a bullet due to a theoretical wind pressure, but the formula could not be "simple." However, Mr. Reid need not be distressed, for it is difficult to conceive any intellectual occupation which would be a more complete waste of ingenuity. Let us consider the real conditions of the problem.

Mr. Reid has not stated them with completeness. It is not sufficient to know the time of flight of the bullet, its size, and weight, the theoretical pressure of the wind, and the angle at which that pressure is exerted. It would be necessary, also, to know the angle at which the rifle is fired, the initial velocity of the bullet, and the space travelled over in its flight. It is obvious at once that the vertical line of flight, if I may be permitted the expression, is not a straight line, but a curve, rapidly accelerating towards the end. If we assume certain arbitrary theoretical figures for initial velocity and strength of wind, there would be no great difficulty in calculating the curve, but it would be a purely imaginary curve, and an utterly useless and deluding calculation. Let us consider the disturbing elements. First, the powder. It would be difficult, if not impossible, to get two charges of precisely and absolutely the same strength. Then the state of foulness would vary. Then the pressure of the wind would always vary in a distance of 500, or 1,000, or 1,500 yards, and in a flight of several seconds; even its very direction would vary at different points in the line of flight, unless in the case of a perfectly open exposed plain.

To all soldiers tempted to indulge in calculations of this nature I would venture to say that there is nothing so likely to mislead. Science and practice should be one and the same thing. If what professes to be science cannot be carried out in practice, it is not true science but bastard science, or pedantry, and the unpractical pedant is even more mischievous in war than the so-called "practical man" in matters of civil life.

Army and Navy Club, March 10 W. HOPE

Glacial Action

IN NATURE of vol. vii. p. 241, you say, "Dr. Dawson thinks that the fiords on coasts, like the deep lateral valleys of mountains, are evidences of the action of waves, rather than that of ice. No glacialist, as far as we know, holds the extravagant belief that fiords have been cut out by ice. They are undoubtedly submerged valleys, and were hollowed out by streams and other atmospheric influences in ages long anterior to the glacial epoch."

A true fiord, like those of Norway, Scotland, and, we may add, the west of Ireland, is nothing but a mountain valley sufficiently depressed for the sea to enter it. I am not a practical geologist, but I have read what appeared to be strong arguments in favour of the belief that the valleys of the Alps have been hollowed out by glaciers. I do not see how any one who sees the quantity of mud that glacier streams bring down, can doubt the great power of glaciers as excavating agents; and the argument is strengthened by the vast moraines, thousands of feet below the present lower limit of the glaciers, and now overgrown with trees, which are to be observed throughout the Alps.

If mountain valleys have not been, in at least a great proportion of cases, excavated by glaciers, how are we to account for the fact that fiords and mountain lakes are almost, if not quite, confined to the higher latitudes? This is especially observable on the west coast of America, which is remarkably unbroken from Vancouver's Island to Chiloe, but broken into fiords from Vancouver's Island northward, and from Chiloe southward.

This observation throws no light on the very different question of the origin of great lowland lakes like those of North America and Africa. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim

The Feeding Habits of the Belted Kingfisher

ON page 48 of Mr. Darwin's "Expression of the Emotions," I find the assertion, "Kingfishers when they catch a fish always beat it until it is killed." We have, in New Jersey, one species of kingfisher, the *Ceryle alcyon*, which is exceedingly abundant for about seven months of the year. For several years I have observed them carefully, both feeding and breeding about the banks of Crosswecksen Creek, and I feel certain that I am correct in saying that I have never seen a kingfisher take its food otherwise than by swallowing it whole, while yet upon the wing. The fish having been swallowed, or at least, having disappeared, the kingfisher will then alight upon the branch of a tree, and will then, frequently, stretch out its neck, and go through a "gulping motion," as though the fish was not entirely in the bird's stomach, or perhaps was only in the œsophagus. In the thousands of instances that I have witnessed, of these birds catching small fish, I never once saw a fish taken from the water, and killed, before being devoured.

So far as my recollection serves me, in the large majority of instances, the kingfisher, after darting into the water and securing a small cyprinoid, will emerge from the stream, uttering its shrill cacophonous scream, as if rejoicing over the delicate morsel it had captured and not scolding at its ill-success, as has been thought; for we have frequently shot them as they rose from the water, and *invariably* found a fish, still alive, in the stomach or œsophagus. Indeed, I cannot see how this characteristic cry of the kingfisher could be accomplished with a fish struggling in its beak. When the fish, from its size or other cause, is retained in the œsophagus until the bird alights, the movements of the bird, to effect the swallowing, are very

similar to those of a pigeon while feeding her young. The neck shortens and swells; the feathers are ruffled and the wings slightly open and shut, two or three times.

So far as my observations of the *Ceryle alcyon* extend, Mr. Darwin's remarks will not apply to that kingfisher.

CHAS. C. ABBOTT

Trenton, New Jersey, Jan. 14

A PETRIFIED FOREST IN THE LIBYAN DESERT

ON the western horizon of the Libyan Desert, as viewed from the summit of the Great Pyramid of Ghizeh, a conical hill stands in solitary grandeur, far removed from the route of desert travellers. This has long been supposed to be the ruins of a pyramid, yet nowhere is it recorded to have been visited by any but the Bedouin tribes who pass within a few miles of it, on the old caravan route to the Faioom. It is enumerated by Lepsius as one of the Pyramids of Egypt, and in a recent work on the Great Pyramid* it is called Dr. Leider's Pyramid, "until a better name be found for it," merely from its having been pointed out to the author by the late Dr. Leider of Cairo, who, however, had never visited it.

The following narrative of a visit to the eminence by Mr. Waynman Dixon, engineer, and Dr. Grant of Cairo, and of their discovery of a very remarkable petrified forest near its base, whose gigantic trees lie scattered about the desert in profusion, has been communicated to us by the former gentleman:—

Leaving the pyramids behind and lighted by the clear silvery moonlight, we set out into the desert by the caravan route to the Faioom, leading up a solitary valley, in the rocks of which are cut ancient Egyptian tanks and mummy-pits. Presently we turn off from the regular track and take our way into the unfrequented desert, steering straight westward for the distant pyramidal hill. The sand of the desert is here hard and compact, and travelling easy, indeed, with the exception of one or two places where the sand is soft and heavy, a wheeled carriage might drive all the way, and to most travellers would be much preferable to camel or even donkey riding.

After many hours hard riding, we at last reach the top of a slight eminence, and across the wide valley in front of us is the place of our destination.

These long valleys, or "wadys," have much of interest about them; throughout may be seen the dry water-courses where the rare rain-showers carry down the sand into the bed, and leave all the little hills and eminences covered with flints as big as potatoes and with surfaces so brightly polished as to give the desert a silvery look by moonlight, or by day to cause the appearance of rippled water where they reflect the sunlight. The zoology and botany, too, of the desert are very interesting. There are numbers of the little "jerboa," a species of rat, with long hind legs and long tail with a tuft of hair at its end, which hops about like a kangaroo. Now and then may be seen a gazelle or two scampering off at the unusual sight of a caravan. A few small birds get a precarious existence, and in the sky an eagle or vulture sometimes wings its way. The insects are few, and the herbage is extremely scant, and it is a marvel what the animals live on. There are here and there in the water-courses small tufts of camel-thorn—a little shrub not unlike a whin, another with a coral-like growth, and now and then a handful of a tough wiry sort of grass, but what these again subsist on it is hard to say, for there is not a shower more than once or twice a year, and for nine months there is no dew while the heat of the sand at midday in summer is over 100 degrees.

Arrived at our destination before daybreak, we dismount from our camels, and while the Bedouins are unloading the baggage, we hasten as fast as our legs, stiff with camel riding, will permit, up the heaps of sand and flints to the summit of the so-called Pyramid, to find on attaining it that it is but the conical end of a prism-shaped hill, stretching westward, and standing boldly out of the desert plain.

Near the top the rock crops out, and appears to be a species of friable sandstone fretted by the weather into curious shapes; but the actual summit is covered with flints and sand, and, what strikes one as being very strange, many fragments of petrified wood.

Taking a general survey from this quoin of vantage, we choose the best spot to the north of the hill to pitch our camp, exposed to the slight north wind which blows incessantly here, and descending its steep sides, at the bottom are surprised to find near the chosen spot three large stone trees lying prostrate on the sand. The largest is 51 ft. in length and 3 ft. 6 in. in diameter at its widest end, and 2 ft. at its smallest; they are branching exogenous trees, apparently a species of pine, and the one before us has the fork of a large branch very complete.

Wandering on up the wady to the north of the hill, named by us "Kôm el Khashob"—the hill of wood—we find the whole desert littered with fragments of petrified wood, from twigs the size of one's finger to pieces of large branches or trunks of trees; and on the flank of the hill to the north are hundreds of immense trees, lying half buried in the sand, some 70 ft. long, and in many instances with part of the bark still attached. All of them are exogenous trees—no single instance of a palm could we discover—and from the absence of roots it may be presumed have been drifted here by the sea. The stratum is apparently sandstone, overlying the limestone of the Nile valley; there are also here and there patches of a dark chocolate-coloured friable mineral with specks of green which looked like copper, but proved on subsequent analysis to be carbonate of iron; beds of what the Arabs call "Gyps" or gypsum, and nodules of an intensely hard black granulated looking stone—not unlike emery stone. The whole geological character suggesting the—possibly delusive—suspicion of the existence of coal under the surface.

Having carefully surveyed this neighbourhood we again climbed the "Kôm el Khashob," taking instruments to measure its height and determine its position; the former of which we found to be 752 ft. above the Nile level at Cairo, 602 ft. above the north-east socket of the Great Pyramid, and consequently about 140 ft. higher than its summit.

Having secured one or two sketches of the hill, and the sun being now near setting, we "fold up our tents like the Arabs and silently steal away." Mounting our camels again, and taking a slightly different route on our return, we pass some ancient solitary well-tombs away in the desert, but without mark or hieroglyphic inscription on them. All the way we notice fragments of petrified wood, and near to the pyramids extensive beds of oyster shells. This forest may almost be said to be a continuation—doubtless going much farther westward than we penetrated—of the well-known petrified forest in the Abbasieh Desert to the east of Cairo, which extends a long way in the direction of Suez, but is inferior both in extent and in the size and perfectness of the trees to that of the newly-discovered forest. The formation of the land here would lead to the supposition that it has been the ancient coast line, and that the trees drifted to where they are now found, and were then left in the briny waters of an evaporating sea or salt lake; and as the fibre of the wood decayed slowly away, the space of each cell has been filled up by the crystallising silica held in solution in the water.

Since the discovery of this forest it has been visited by many Europeans in Cairo, and English travellers, and to geologists especially it is well worthy of a visit. It may easily be reached from the Great Pyramid

* "Life and Work at the Great Pyramid," by Prof. Piazzi Smyth, F.R.S.

either by donkey, camel, or horse, and is distant under three hours from it—a journey which in the winter may with comfort be accomplished in one day from Cairo. Indeed, if his Highness, the Khedive, who has done so much for the comfort of travellers in making a magnificent road to the pyramids, were to extend it for some half mile farther through the tract of soft sand, carriages could easily drive all the way to the Kôm el Khashob. The locality is now well known to the Pyramid Arabs, and most able and intelligent guides will be found in Ali Dobree, Omar, or others of this Bedouin tribe.

HUNTERIAN LECTURES BY PROF. FLOWER

LECTURES VII. VIII. IX.

THE family Edentata includes the Bradypodidæ, Dasypodidæ Myrmecophagidæ, Manidæ, and Orycteropodidæ, the first three being from the new world and the last two from the old. Considering them shortly, the Bradypodidæ are leaf-eaters; they have five molars above and four below, no other teeth being present. each tooth is a cylindroid column with a persistent pulp, and is surrounded externally by a harder layer, which causes the free surface to become cupped during wear. There is a peculiar descending process from the incomplete zygoma. The number of the vertebræ is great, their spinous and other processes are but little developed as the back is not much employed in supporting the body. There are extra articular surfaces on the lumbar vertebræ of the three-toed sloth, not found in the two-toed species. The clavicles are sometimes rudimentary, never complete. A bony arch joins the acromial process of the scapula to the coracoid, and the distal end of the clavicle in Bradypus is attached to the latter, a peculiarity which has been explained by Mr. Parker. The supra-spinous notch is converted into a foramen by a bony arch running over it, and there is a supra-condyloid foramen in the humerus of Cholopus only. Considerable rotation of the radius is possible; the hand is peculiarly modified, the fingers being bound together. It is generally stated that the trapezium is anchylosed to the scaphoid, which is very long, but that such is not the case is proved by the examination of the young animal; the trapezium, in fact, anchyloses with the first metacarpal bone. In Cholopus the second and third toes are only present. The ilia are broad, the femur short and with no ligamentum teres; some peculiar small bones are found round the knee. The tibia and fibula are firmly united, but not anchylosed; both genera have three toes on the hind foot. The inner surface of the fibular maleolus sends inwards a conical process, which acts as the pivot in which the externally cupped astragalus is hinged, and thus allows of a great range of movement of the foot. The peculiarities in the number of the cervical vertebræ are well known, no similar abnormalities are found in the fossil genera.

The other Edentata are not purely vegetable feeders; they eat ants and other animal food. In the Dasypodidæ the teeth are numerous, and the cervical vertebræ tend to anchylose together. As in the whole family the sternal ribs are ossified. The degree of development of the carapace is indicated by the size of the vertebral processes, and an extra series of articulations, as in the ant-eater and sloth, occurs in the lumbar region. In Myrmecophaga there are no teeth; the hind feet are quite normal, the front very peculiar, possessing five toes, and claws on the middle three. In the Old World forms, Manis and Orycteropus, there is no extra interlocking of the lumbar region, and in the former no teeth. Orycteropus possesses teeth, each of which may be said to be a compound tooth, each element of which has a persistent pulp.

Hitherto no true sloths have been found fossil in South America; they were then represented by the Gravigrada, which are so termed in contra-distinction to the Tardigrada; they abound in the Pampas of Buenos Ayres, and are found as far north as the United States. *Megatherium* was the first of these large animals discovered, and the original skeleton, obtained in 1789, is now at Madrid. Since then several entire skeletons have been obtained, of which two very fine specimens are to be seen at the Museums of Turin and Milan. Those of the College and of the British Museum are partly from casts. Leidy has placed the North American animal in a distinct species (*M. mirabile*), on account of its geographical distribution, but he is unable to detect any osteological peculiarities, The only teeth in this animal are five molars with persistent pulps above, and four below on each side, as in Bradypus; and they form a continuous series. Each tooth has a double transverse ridge, the hollow of which fits the ridges in the opposite jaw. These ridges do not disappear as the animal gets old, but are permanent on account of the dentine not being uniform in density, the middle being softer than the sides, and therefore wearing away more readily. The teeth in the middle of the series are the largest. The skull is small considering the size of the animal, and the brain-case remarkably so. The brain itself, as known from a cast of the interior of the cranium by Prof. Gervais, closely resembles that of the sloths. The skull is very much elongated, the anterior condyloid foramina being large, it is probable that the tongue was so also. The palate was extremely narrow, and the premaxillary portion extensive. An enormous bony process descended from the zygoma which is also a peculiarity of the other members of the same family. The ramus of the lower jaw was immensely high. In the megatherium only is the molar portion of the mandible of unusual depth, and this is to hold the continually growing teeth. There are seven cervical, sixteen dorsal, three lumbar, five sacral, and eighteen caudal vertebræ; the lumbars, as in Myrmecophaga and Bradypus, possess interlocking processes; the whole column resembles that of the former of those animals more than the latter. The tail was strongly developed, and chevron bones existed on the neural surfaces of the caudal vertebræ. As several scutes were found with the bones of Megatherium, and as the different processes of the vertebræ were strong, it was at one time supposed that this animal possessed a shield, but there is no doubt that the scutes were those of Glyptodon, and the vertebræ do not resemble those of the Armadillo. The sternum was composed of seven pieces, and the clavicles large and well developed, being the only examples of these bones, which are bigger than those of man. As in the sloths, the acromion joined the coracoid, and the supraspinous foramen was strongly bridged over. In its distal limb segments the animal was peculiar. There was no supracondyloid foramen to the humerus; the radius and ulna were free; all the bones of the carpus were represented; the pollex was lost, and the other digits were present; the fourth and fifth metacarpals were elongated, the proximal phalanges very short, and the distal of the index, middle, and ring fingers constructed to carry huge claws, which differed from those of the cats in being flexed instead of extended when they were not in use, upon which depends the difference in the shape of their articular surfaces. The second and third phalanges of the middle finger were anchylosed, and a phalanx was missing in the fifth finger, which did not carry a nail. The pelvis presented the peculiarities of the sloths, and was very large. The femur had a small pit for the insertion of the ligamentum teres. The tibia and fibula were anchylosed at both ends. All the leg bones were massive. The foot was very peculiar, the animal must have rested on its outer edge. The os calcis was very large, with the calcarcaneal process going nearly as far backwards as the toes forwards. The

ankle, as in Megalonyx and the other allies of Megatherium, was not pivoted as in the sloths, but the inner malleolus was quite cut away and replaced by a slightly concave articular surface looking downwards and a little inwards, which was continuous with that of the lower ends of the tibia, a ridge intervening. The superior surface of the astragalus was consequently of a peculiar form, possessing a longitudinal median groove. The first and second digits of the foot were missing, and a claw was present only on the third, in which the middle and distal phalanges were anchylosed; there were two phalanges on the fourth toe, and only one was present on the fifth. As to its habits, there is no doubt that Megatherium was not a burrower as supposed by Pander, nor arboreal as suggested by Lund, but that Prof. Owen's hypothesis is correct in which he considers that it was terrestrial, feeding on trees, which it uprooted or broke boughs off.

Mylodon possessed the same number of teeth as its allies and the sloths, but the anterior pair in the upper jaw were separated by a considerable interval from those behind. All the teeth were more or less cylindrical and had persistent pulps; the worn surfaces were cupped and not ridged, because the dentine was softest in the centre; the fourth lower molar was elongated and grooved. Several species of this genus have been found, one only in North America. Gervais has divided off some with more separated anterior molars into a new genus, but Burmeister does not think this justifiable. The College of Surgeons possesses a very good skeleton, almost perfect, obtained in 1841. The skull was very slothlike, the fore part being truncated and the nasal fossae open. There was a large descending process of the zygoma and an ascending one; the bony arch was complete. There was no enlargement of the molar region in the lower jaw like that of Megatherium. Air cavities existed all round the brain-case, as in the elephant, but to a less degree The vertebræ were C. 7, D. 16, L. 3, S. 7, and Caud. 21. The lumbar vertebræ were anchylosed together to the last dorsal and to the sacrum. The tail was long and powerful; the limbs much like those of Megatherium, but differed in the radius and ulna being separate, as were the tibia and fibula. In the fore-foot Mylodon had the five digits, with claws on the first three. The ankle was as in Megatherium; the hallux only was missing, and the fourth and fifth toes did not carry claws.

Scelidotherium was smaller and altogether lighter built than those mentioned above; the teeth were equidistant and elongated from before backwards as was the head. The rest of the skeleton much resembled Mylodon, but the lumbar vertebræ were not anchylosed.

Megalonyx was a North American form. Prof. Leidy has described it fully. There was a great gap between the anterior tooth, which was large and much like a canine, and the other molars, whose number were the same as in the sloths. The animal had longer and slenderer limbs than those described above and therefore more nearly approached the sloths.

[In last week's report of these lectures, *Thylacoleo* is misprinted *Thylacoles*, and the animal is stated to have 32 instead of 2 molar teeth in the lower jaw.]

FAUNA OF THE NEW ENGLAND COAST

PROF. VERRILL, in discussing the collections made by the parties of the United States Commissioner of Fish and Fisheries upon the Coast Survey steamer *Bache* during her cruise off the coast of New England, in the summer of 1872, sums up by stating that they represent six distinct faunas and sub-faunas as follows:—

(1) The surtace fauna outside of the banks, and, at certain times, even extending over their outer slopes. This is essentially the same as the fauna prevailing over the entire surface of the central parts of the Atlantic Ocean, and shows very clearly the direct effects of the Gulf Stream.

(2) The surface fauna inside of the Banks, which is decidedly northern in character, very similar to that of the Bay of Fundy. The contrast between the two shows that the Gulf Stream is almost entirely turned aside by the Banks, and has comparatively little effect upon the fauna between them and the coast.

(3) The fauna of the St. George's Bank itself. This is decidedly boreal in character, and essentially identical with that of the Bay of Fundy at corresponding depths, on similar bottoms, and in regions swept by strong currents. The fauna of the south-western part, however, is less boreal than that of the north-western.

(4) The fauna of the Le Have Banks, and off Halifax. This, even at the moderate depth of twenty fathoms, is decidedly more arctic in character than that of the St. George's or the Bay of Fundy at similar or even greater depths.

(5) Between the St. George's and Le Have Banks and the coast there is a great region of cold and comparatively deep water—in places more than 100 fathoms in depth—with a bottom of mud and fine sand, and communicating with the great ocean-basin by a channel between the St. George's and Le Have banks, which is comparatively narrow and, in some places, at least 150 fathoms deep. This partially inclosed region has, physically and zoologically, the essential features of a gulf, and may be called the St. George's Gulf. The deeper waters of the Bay of Fundy are directly continuous with those of this area. The fauna of this Gulf and of its outlet is peculiarly rich in species new to the American coast, and nearly identical with that of the deeper waters of the Gulf of St. Lawrence, and agrees very closely with that found on muddy bottoms, and at similar depths, on the coasts of Greenland, Finmark, and Norway.

He also presents additional generalisations as follows:—

(6) The deepest dredging, in 430 fathoms, was outside of the St. George's Banks, on the slope of the actual continental border, and within the limits of the true Atlantic "basin." The fauna there is especially rich and varied, decidedly northern in character, and agrees closely with that of similar localities and depths on the European side. The animals were mostly such as inhabit bottoms swept by strong currents in the Bay of Fundy.

(7) Everywhere over the banks, and especially on the southern slopes, the difference between the bottom and surface amounts to from 15° to 20°, or even more; the surface temperature being usually from 60° to 72°. The temperature of the air was very near that of the water, generally one or two degrees higher.

(8) No such contrast of temperature was found inside ot the Banks in the St. George's Gulf or the Bay of Fundy; the difference seldom being more than ten degrees, and often, especially in the Bay of Fundy, less than five. The surface temperature at corresponding dates in the Bay of Fundy were 48° to 53°, showing an average difference of about 20° for the surface temperature in the two regions, while the average bottom temperatures do not appear to differ materially.

(9) The high surface temperature of the Banks is evidently due chiefly to the direct influence of the Gulf Stream.

(10) The very low surface temperature of the Bay of Fundy is largely due to its *geographical position*, and the *absence* of any appreciable influence from the Gulf Stream, but it is no doubt intensified by the powerful tides, which are constantly mixing the cold bottom water with that of the surface.

The facts hitherto observed do not seem to warrant the assumption that an "arctic current," properly so-called, as distinguished from the tidal currents, enters the St. George's Gulf or the Bay of Fundy. The action of

the tidal currents in bringing up the cold bottom waters of the ocean is perhaps a cause sufficient to produce most of the coldness of the water in this region.

ON DINOCERAS MIRABILIS (MARSH)

A SHORT time ago we gave a note respecting one of the recently-discovered gigantic fossil mammals from the Eocene of Wyoming in the region of the Rocky Mountains; the accompanying woodcut, copied from a paper by Prof. Marsh, on this extraordinary extinct animal, named by him *Dinoceras mirabilis*, will further assist in making its peculiarities easily understood.

The animal must have been nearly as large as the elephant, to which its limb-bones were very similar. The only teeth it possessed in the upper jaw, were a pair of well-developed canine tusks, and six pairs of small molars, whose crowns were formed of two transverse ridges, separated externally, but meeting at their inner extremities.

DINOCERAS MIRABILIS

The frontal region of the skull was concave, on account of the lateral projection upwards of a bony ridge or crest on each side, which posteriorly developed into a large osseous process that may have been a horn core but perhaps was only covered with thick skin, and acted like the fibrous pads on the cheeks of the wart-hog, to shield the thinner skull from direct blows. Behind these the crest extended back beyond the level of the occipital condyles. The maxillaries each bore a conical process, which in a profile view is evidently seen to be directly above the root of the canine tusk, and supported it; it probably carried a horn. At the anterior extremities of the nasals were also two smaller horn cores. The horns must have been of a character very different from those in the rhinoceros, in which animal, however long they may be, they are only supported on a roughened surface of bone; if they resembled those of the cavicorn ungulata, from analogy we must suppose that they were small, for in those animals there is a close relation between the size of the core and that of the horn which it carried.

There were no postorbital processes to the frontal bones. The zygoma was completed in front by the malar, the lachrymal was large, and formed the anterior border of the orbit; its foramen was exserted. The infraorbital foramen must have been behind the zygomatic ridge, as it does not appear in any of the drawings. The premaxillaries did not carry teeth; they sent forward two branches, which partially enclosed the sides of the external nares; the upper branch joined the nasal, and the lower, as in the Ruminants, continued free, and probably carried a pad. Prof. Marsh gives no illustration of the mandible, and only remarks of it that "the lower jaw was slender and the tusks small." The limbs were short, the fore limbs shorter than those behind. The radius did not cross the ulna so obliquely as in the elephant. In the head of the femur there was not any pit for the insertion of the round ligament. The great trochanter was flattened and recurved; the third trochanter was absent. The tail was short and slender. The ribs had rudimentary uncinate processes.

Prof. Marsh feels justified in placing Dinoceras in an order Dinocerata, distinct from the Proboscidia, on account of the absence of upper incisors; the presence of canines and horns; the absence of large cranial air cavities; the malar forming the anterior portion of the zygoma; the absence of a proboscis, which could not have been necessary in an animal that could easily touch the ground with its nose, and other less important differences.

This *Dinoceras* of Marsh is the *Eobasileus* of Cope and the *Uintatherium* of Leidy. The shortness of the published descriptions prevents us saying more about it at present.

THE TROGLODYTES OF THE VEZERE *

III.

Our Troglodytes of the latest epoch had, in fishing, another resource unknown to their predecessors. Their different stations contain a large number of fish bones; but it is remarkable that all these fish were salmon. Now the salmon in these days neither frequent the Vézère nor the part of Dordogne where that river joins the sea. At some leagues below the confluence, not far from Lalinde, in the centre of Dordogne, there is a bank of rocks, which, at high water, forms a rapid, and at low water a regular fall, called, The Leap of the Gratusse. The salmon do not pass this boundary, and, as it did not stop them at the epoch of the Troglodytes, we must conclude that, since that time, the level of the Dordogne has fallen, either by hollowing out its bed so as to lay bare the bank of rocks, or by losing part of its volume of water. We are led to believe that the fishermen of that time did not use nets, for with a net could be caught fish of all sizes. We thus understand why they could only catch large fish, and why they chose, among these, the kind they preferred. Had they any fishing boats? We have as yet found no proof of such. And besides, the Vézère is sufficiently enclosed for the large fish to swim along the banks within reach of the harpoons.

The harpoon of our Troglodytes was a small dart of deer-horn, very similar to the large barbed arrows, except that it was only barbed on one side. A little notch at the base enabled the fisherman to secure the cord which he held in his hand (see above, Fig. 10). The barbs are intended to secure the fish which it has struck. Why are these barbs all placed on the same side? Is it to diminish the width of the dart and make it more penetrating? This I cannot venture to affirm.†

* Continued from p. 325

† One of my colleagues of the French Association, M. Lecoq de Boisbaudrau, who did me the honour of being present at this lecture, communicated, the following day, to the Section of Anthropology, a very interesting note on the mode of action of the unilateral barbs of the harpoon. While the harpoon is traversing the air, these barbs cannot make it deviate sensibly; but directly it enters the water, the unequal resistance it meets there must necessarily change its direction. It seems, then, that the fisherman who aims straight ought the most frequently to miss his aim. But M. Lecoq de Boisbaudrau reminds us of the well-known experiment of the straight

After fishing and hunting, they returned to the cave for their meals.

In the whole extent of the floor of the caves, at every level, the stratum which encloses broken bones contains likewise an enormous amount of particles of coal. This mixture is so universal, so uniform, that it is difficult to believe that the Troglodytes only made fires for warming themselves. They must have lit their fires every day, and in all seasons; and hence it is more probable that they used them for cooking their food.

We do not know how they produced fire, whether they drew it from flint or from wood heated from friction.

FIG. 13.—Bone harpoon of the Terra del Fuegans.

Neither do we know how they cooked their food. They had no earthenware, and could not boil their meat on the fire. They did not roast it, for hardly a solitary calcined bone has been found, and then it has evidently been accidentally reduced to this state. Perhaps they boiled it in wooden vessels, in which water can be brought to the boiling point by putting into it pebbles made red hot in the fire. But it seems to me more probable that they cooked it under the ashes, as many uncivilised nations do to this day.

They enjoyed the brains of animals and the marrow in the long bones, for all the heads are broken, and all the medullary bones (to the exclusion of all others) are methodically divided. The marrow in bones is a dish relished by all savage nations. They break the long bone in a particular manner, and the chief sucks the marrow first. Our Troglodytes had little flint maces with cuneiform edge; these were a kind of hatchet for breaking the bones. There is, besides, another utensil in deer-horn, which was probably used for extracting the marrow (Fig. 14)

FIG. 14. FIG. 18. FIG. 17. FIGS. 15, 16. FIG. 21. FIG. 19. FIG. 20.

Fig. 14.—The marrow spoon. Figs. 15 and 16.—Needles. Fig. 17.—Hunting tablet. Fig. 13.—Account tablet. Fig. 19.—Baton of command with a single hole (reduced a third). Fig. 20.—Baton of command with four holes (reduced a third). Fig 21.—The pogamagan of the Esquimaux (reduced a fourth).

The Troglodytes, after their meals, left the bones spread about the floors of their caves. In a warm climate, these remnants would have exhaled an insufferable odour, but we must not forget that the temperature was then lower than it is now, and we must likewise confess that cleanliness was not the predominant feature of the men of those days.

Thanks to this uncleanly habit, the floor of their caves furnishes us with complete information as to their food. The flesh of the reindeer was their principal nourishment; they ate besides horses, aurochs, several kinds of oxen, chamois, wild goats, and even some carnivora; their predecessors did the same; but these had fish in addition, and the improvement in their bows and arrows enabled them to bring down game on the wing. Among

stick which appears broken when plunged obliquely in the water. In consequence of the refraction of the rays of light, the image of the fish is displaced, and in aiming straight at that image, one would miss one's aim. Here, then, are two causes of error. Now it is clear that, if they act inversely, they may compensate each other; and M. Lecoq de Boisbeaudrau demonstrates that when the unilateral barb is turned upwards, it brings back the harpoon towards the object. This arrangement in the harpoon would then be intended to rectify the aim, and this would credit our Troglodytes with a great power of observation.

The inhabitants of Terra del Fuego [still use a harpoon] with unilateral barbs (see Fig. 13).

the remains of their repasts are found a variety of birds.

Among these innumerable *debris* of bones, there is not a single fragment of a human bone. Our good Troglodytes were, therefore, not anthropophagi. They must have fought occasionally to defend or enlarge their hunting territory; nevertheless, their equipment was more that of huntsmen than of warriors.

In reviewing their panoply, it is evident that the most dangerous weapons, those which could be available in a hand-to-hand fight, are the most rare, and we remain convinced that they were a pacific race.

It might be concluded that they wore no clothing, because all the men represented by their artists are completely naked; but that proves absolutely nothing. Do we not know that the Greeks often represented their gods and their heroes in a state of nudity?

In the Troglodyte caves have been found all the requisites for needlework. They had needles of bone and of deer-horn. Some were only piercers, like a shoemaker's awl, others were provided with an eye for holding the thread (see Figs. 15 and 16). There were some very fine ones. A small needle case has been found, made of a bird's bone, which could contain a number of them. They are supposed to have been obtained from the metacarpus of a horse, on which several longitudinal and parallel incisions, with a fine saw, have extracted little, narrow, even spiculæ of long bones. The work was not complete; but it is evident that these slender spiculæ could only be destined for making needles. The threads used in sewing were doubtless of different kinds. Did they use vegetable fibre or fine lashes of leather? It is possible and even probable. What is nearly certain is that our Troglodytes made threads or at least strings with the substance of tendons.

I do not know whether the Troglodytes utilised thus the nerves of the reindeer, but they carefully detached the long tendons with a certain little blow which produced on the surface of the bone a superficial abrasion of a very regular shape. This abrasion, always the same, has been found on different bones, but the spots where it exists have this in common, that they mark the place of a long tendon. It is, therefore, the proof of a methodical operation, which was doubtless practised before giving the meat to the cook, and which was probably destined to prepare threads for sewing.

Sewing is a proof of clothing, and not of that primitive clothing which consists of the skin of some animal thrown over the shoulders, but of a more complete dress, formed by the joining of several skins. The abundance of needles and piercers, and of scrapers which helped to prepare the skins, proves that the use of clothing must have been general. They also wore ornaments, which perhaps served as marks of distinction. These were necklaces or bracelets, formed of shells perforated and threaded.

Most savage nations have the habit of painting and tattooing themselves; we have no right to despise them on this account, for tattooing is still held in honour in the popular classes of the most civilised countries, and it is even hinted that ladies in the upper circles have not quite forgotten the art of pencilling. We must not then wonder at finding similar fashions among the Troglodytes. Their caves contain numerous fragments of the red stone which we call *red ochre*; the stripes frequently found on these fragments prove that they have been scraped. They therefore prepared a red colour, which was in constant use, and which probably served to ornament the body with pictures.

I have already said that Troglodytes were not nomads. Some individuals may doubtless have undertaken voyages, but the entire tribe never went far from their caves. It was then by means of barter or commerce that certain foreign articles were imported. The numerous perforated shells of which the necklaces and bracelets were composed, were all foreign to the locality. Most of them belonged to the species *Littorina littorea*, and came from the shores of the Atlantic, where they are still very abundant. They were brought quite fresh, for they had their natural colours, which are preserved to this day in the floors of the caves. Other shells pierced in like manner with one hole, belong to five extinct species only to be found in *faluns*, and which date from the Miocene epoch. They are quite discoloured and broken into molecules; and the traces of rolling which they sometimes present, prove that they were fossils long before they were extracted from their tertiary beds to ornament man. Now the *faluns* which contain these five species are not found in the region of the Vézère. The nearest are those of Touraine, and it was from thence, in all probability, that our Troglodytes imported this toilet necessary. There have been likewise found in three stations, and principally at Upper Laugerie, little pieces of rock crystal; this substance must have come from the Pyrenees, the Alps, or

FIG. 22.—Combat of Reindeer.

the mountains of Auvergne. The foreign relations of the Troglodytes were therefore rather extensive.

Had they any religious faith? Nothing has been found in their habitations which could refer to any religious worship. But they wore talismans or amulets. These were a canine or incisive tooth of wolf, reindeer, ox, or horse. A hole, carefully bored at one extremity of the tooth, served for passing the string by which it was suspended.

At the same epoch, but in a different spot, certain funereal rites were observed. They placed the dead in a cave, whose narrow opening was closed by a flag-stone. In front of this stone was a little esplanade on which the afflicted relatives consoled themselves with feasting. This kind of consolation has been perpetuated from age to age, and it has not yet disappeared from among us.

At present we know of but one burying ground of the Troglodytes of the Vézère; it is that of Cromagnon. It is under a shelter and not in a cave; by the side of the corpses were placed carved flints and ornaments in shells, but there is no trace of a stone door.

The society of the Troglodytes was numerous, and hierarchically organised. There were several orders of dignitaries. The proofs of this organisation are to be found in the three stations of the last epoch—the Eyzies, Lower Laugerie, and the Madelaine. They are large pieces of deer-horn, carved artistically, and designated in general terms under the name of "batons of command." These batons are numerous. Here are several, and you can see that they have a uniform type. Their whole surface is richly adorned with various drawings, representing animals or hunting scenes. They are less thick than wide, and the care that has been taken to diminish the thickness proves that they sought lightness rather than solidity. Then, again, the greater number, though not all, are pierced with large round holes, varying in number from one to four (see Figs. 19 and 20). The purpose of these very curious objects is still a disputed point, but most probably they were used as insignia. They indicate the sceptre, borne among the ancients, not only by the king, but by the chiefs of a less elevated rank. The dignity of marshal is to this day characterised by a baton. The batons of command are too numerous to allow of their being considered a sign of royalty. They are only signs of hierarchical distinction. The holes indicate the grade.

This superposition of grades or ranks, a sure sign of a numerous society, might doubtless be utilised in times of war, but it is very probable that it referred primarily to the appointment of hunting expeditions, for the chase was the essential element of public prosperity, and it was necessary to organise it systematically in order to secure food for the community.

Thanks to the organisation and administration of which we recognise the proofs, the society of Troglodytes, though numerous, lived in comfort. Food was sufficiently abundant to enable them to choose the best pieces, and reject those of an inferior quality. Thus, they despised the feet of animals, which nevertheless contain, in the bones and tendons, a remarkable quantity of alimentary matter. The destruction of dangerous animals had given security; the improvement in hunting had given abundance. It was no longer necessary for the entire tribe to devote their whole time, energy, and intelligence to the urgent necessities of daily life. They could rest occasionally. They could have leisure hours, and leisure, joined to intelligence, produces the arts.

(*To be continued.*)

NOTES

THE names of fifty-three candidates which, in pursuance of the Statute, were read out at the meeting on Thursday last, is a proof that the desire to enter the Royal Society does not abate. Out of this large number the Council will, in April, select fifteen whom they will recommend for election; and the names of these will, as usual, be made known at the meeting of the Society on the first Thursday in May. The selection ought not to be difficult, notwithstanding that in perusing the names we mark not a few instances of misplaced ambition, and indications that an obvious misunderstanding as to the qualification for membership exists on the part of the candidates. It must not be forgotten that the Royal Society is *not* a kind of superior College of Surgeons or Physicians or Preceptors; in fact, that something higher even than the art of healing or teaching must be looked for, namely, research, and the enlargement of the boundaries of knowledge. As in the majority of cases non-election is inevitable, it is as well that the number should be large: disappointment is, thereby, reduced to a minimum. But here is the list, and our readers may judge for themselves. The election day is fixed for June 12. W. Aitken, M.D.; Sir Alexander Armstrong, K.C.B., M.D.; R. Stawell Ball, LL.D.; Rev. A. Barry, D.D., D.C.L.; E. Middleton Barry, R.A.; J. Beddoe, B.A., M.D.; I. Lowthian Bell; G. Bishop, F.R.A.S.; F. J. Bramwell, C.E.; W. Lawry Buller, Sc.D.; Capt. E. Kilwick Calver, R.N.; A. Carte, M.A., M.D.; W. Chimmo, Commander R.N.; H. Davies, M.D; Henry Dircks; R. L. J. Ellery, F.R.A.S.; J. Fayrer, M.D.; P. Le Neve Foster M.A.; T. Minchin Goodeve, M.A.; L. D. Brodie Gordon, C.E.; Lt.-Col. J. A. Grant, C.B.; J. Eliot Howard; Rev. A. Hume, LL.D.; Edmund C. Johnson, F.R.C.S.; Lord Lindsay, F.R.A.S.; Clements R. Markham, C.B.; W. Mayes, Staff-Commander R.N.; E. J. Mills, D.Sc.; R. Stirling Newall, F.R.A.S.; G. E. Paget, M.D., D.C.L.; F. Polkinghorne Pascoe, F.L.S.; O. Pemberton, M.R.C.S.; Rev. S. J. Perry; J. A. Phillips, F.G.S.; W. O. Priestley, M.D.; C. B. Radcliffe, M.D.; A. Rattray, M.D., R.N.; E. J. Reed, C.B.; W. Chandler Roberts, F.C.S.; G. W. Royston-Pigott, M.A., M.D.; W. Westcott Rundell; Osbert Salvin, M.A.; Major-General H. Y. Darracott Scott, R.E., C.B.; J. Spiller, F.C.S.; Hon. J. W. Strutt; G. J. Symons, F.M.S.; Sir Henry Thompson, F.R.C.S.; E. T. Truman, M.R.C.S.; F. H. Wenham; Capt. C. W. Wilson, R.N.; H. Woodward, F.G.S.; Lieut.-Col. A. H. P. Stuart Wortley; J. Young, F.C.S.

M. BERTHELOT, the eminent chemist, has been elected a member of the French Academy.

THE reports of the Hunterian Lectures which appear in NATURE are not written by Prof. Flower.

THE Belgian Academy announces the following as subjects for prizes to be awarded in 1874:—1. To perfect in some important point, either in its principles or its applications, the theory of the functions of an imaginary variable. 2. A complete discussion of the temperature of space, based upon experiments, observations, and the calculus, stating the grounds for the choice made between the various temperatures which have been attributed to it. 3. A complete study, theoretic and, if necessary, experimental of the specific absolute heat of simple and compound bodies. 4. New experiments upon uric acid and its derivatives, principally in relation to their chemical structure and their synthesis. 5. (*a.*) A succinct critical *résumé* of existing observations of the *Mucedineæ*. (*b.*) The exact determination—applied to only a single species—of the part which is due, first, to the essential nature of the vegetable (its specific energy), and next to the external conditions of its development. (*c.*) A positive proof, or a satisfactory disproof, of the statement that the fungi of fermentation in certain circumstances, can be transformed into fungi of a higher class. 6. A paper on the Plutonic rocks, or those that are considered such, of Belgium and the French Ardennes, especially in relation to their composition. The prizes for Nos. 1, 4, and 5 will be a gold medal of the value of 600 francs; for No. 6, one of the value of 800 francs; and for No. 3, a medal worth 1,000 francs. The manuscripts, which may be in either French, Flemish, or Latin, must be sent to M. Ad. Quetelet, perpetual secretary, before August 1, 1874.

WE understand that Mr. F. J. M. Page, B.Sc., Assoc. R.S.M., F.C.S., has been appointed chemical assistant to the Brown Institution, under Dr. Burdon Sanderson. It is with much pleasure that we announce this, as it argues well for the attention which will be paid to physiological chemistry, a subject which of late years has received comparatively little attention in England.

AN examination for a Natural Science Scholarship for 60*l.* per annum will be held at Gonville and Caius College, Cambridge, on April 3 and 4. The subjects:—chemistry and experimental physics, zoology with comparative anatomy and physiology, botany with vegetable anatomy and physiology. The Scholarship is tenable for two years, but the tenure may be prolonged for another year if the Scholar sufficiently distinguish

himself in the annual College examinations. No person will be eligible who has commenced residence in the University, and the successful candidate will be required to enter his name at the College forthwith, and begin residence in October next. For further particulars apply to Dr. Drosier, Gonville and Caius College.

WE have received from the Science and Art Department a thick pamphlet containing the prospectus of Sir Joseph Whitworth's Scholarships for mechanical science. These Scholarships are of the value of 100*l.* a year, and are tenable for three years, and the competition is open to all Her Majesty's subjects, at home, in India, and in the Colonies, who have not completed their 26th year, though we see that after the next examination (May 1873) the limit of age will be 22 years. Ten Scholarships will be competed for this year, at examinations which will be partly in practical workmanship, and partly in theoretical subjects. Those who desire detailed information, should procure a copy of the very full prospectus.

THE examiners for the Burdett-Coutts Scholarship, Prof. Phillips, Prof. Odling, and Mr. E. Chapman, M.A., have recommended to the trustees for election, Mr. Edward Cleminshaw, Postmaster of Merton College. The Scholarship was founded by Miss Burdett Coutts for the promotion of the study of geology and of natural science as bearing on geology. The Scholarship is tenable for two years. Mr. Cleminshaw was placed in the first class by the examiners in the Natural Science School in December last. He received his Scientific training in the Applied Sciences department of King's College, London.

MR. J. J. TAYLOR, of Giggleswick Grammar School, has been elected to the Junior Studentship in Natural Science at Christ Church, Oxford. This studentship is of the annual value of 100*l.* Mr. Taylor's scientific training has been under the direction of Dr. W. Marshall Watts, the Science Master of the School.

WE understand that Mr. Osbert Salvin, F.Z.S., is about to return to his old collecting quarters in Guatemala for a short period. Mr. Salvin's valuable contributions to the fauna and flora of Central America are well known, but we trust that he will still be able to add to his former discoveries, extensive as they have already been.

THE Russian Government has determined to send a scientific expedition with the military force to Khiva. It will leave in the course of the present month.

WE have received a copy of the syllabus of a course of lectures on botany to be delivered in the Royal College of Science, Stephen's Green, Dublin, by Prof. W. R. McNab. It differs from most other similar courses of lectures in its arrangement, being closely modelled after Sachs's "Lehrbuch." Commencing at once with the morphology of the cell, it proceeds then to the morphology of tissues and the external morphology of plants; then to the special morphology of the various groups of Thallophytes, Characeæ, Muscineæ, Vascular Cryptogams, and Phanerogams; and finally to physiology. Though, perhaps, erring on the side of two great minuteness for a short course of lectures, it is admirable in its comprehensiveness and scientific arrangement.

DR. DAVID MOORE, the Director of the Botanic Garden of the Royal Dublin Society at Glasnevin, has made a successful attempt to propagate the well-known parasite of the South of Europe, *Loranthus europæus*, on oak-trees in the gardens. This has frequently been attempted previously by horticulturists in this country and in Ireland, and Dr. Moore deserves great credit for the energy and perseverance with which he has carried his efforts to a successful issue. The common mistletoe, which is not a native of Ireland, has also been successfully introduced by Dr. Moore and others into that country, and is now rapidly spreading; and in the Botanic Gardens *Lathræa squamaria* and two species of *Orobanche* have also been permanently established, and six species of *Cuscuta* or dodder more transitorily.

TWO fine plants, both from Moreton Bay, are at present objects of interest at Kew. The tree of *Araucaria Bidwilli*, in the temperate house, has produced cones for the first time in Europe. It was one of the two original plants brought to this country in 1842 by Mr. Bidwill, the other having been purchased for 100 guineas by the Duke of Northumberland. The Kew tree is about 26 ft. high, and its branches cover a circumference of about 60 ft. The seeds are very important articles of food to the aboriginal inhabitants, and the property of the tribes in individual trees of the Bunya-bunya is the only possession they have, and is the commencement of a communal system amongst them. *Dendrobium Hillii* is the principal feature in the orchid house. The large mass in flower has as many as twenty pale yellow racemes, some being as much as 2 ft. in length.

THE Report of the Ashmolean Society for 1872 shows that a little more life has been infused into that society during the past year, though we think there is still considerable room for improvement, and hope that next year's report will be able to speak of a considerably greater amount of work of permanent value having been done. During the year 1872 the Society has held four General Meetings, at which the following communications have been received:—A paper "On House Temperatures," by Prof. Phillips; a note "On the Meteors of April 19, 1872," by Mr. Lucas; a paper "On the Breaks of Continuity in the Mean Daily Temperature in the months of April and May," by the Radcliffe Observer; a paper "On the Sulphur Compounds in Coal Gas, and the means of removing them," by Mr. A. G. Vernon Harcourt, F.R.S.; a paper "On the Flint implement-bearing beds of St. Acheul," by Mr. James Parker; a paper by Mr. Heathcote Wyndham "On the Recent Eruption of Vesuvius," illustrated by oil paintings of sketches made by the author on the spot.

MR. R. W. THOMSON, C.E., the inventor of the road steamer, and a man in many ways remarkable, died at Edinburgh on the 8th inst., in the 50th year of his age.

THE new strip of garden belonging to the Zoological Society on the north side of the Regent's Canal, is now being put into order. The bridge over the canal is already finished, and the new lodge opposite Primrose Hill only wants the entrance gates and turnstiles to make it complete. We understand that it will be open to the public on Easter Monday.

WE see from a leader in the *New York Tribune* of February 26, that the astounding number of almost 200,000 copies of the three cent reprint of Prof. Tyndall's lectures on light has already been sold, and that orders are still pouring in for them from all parts of the States. The *Tribune* also publishes a large number of letters from people throughout the States asking the letters to be sent them, and justly praising the enterprise of the paper in so energetically and wisely meeting a wide popular want. It reminds one of the demands occasionally seen on this side of the water for the last sensation novel or the latest news of the most recent poisoning case. Such a wide-spread taste for *Light* literature of the stamp purveyed by the *Tribune* to its multitudinous readers, is a healthy sign, and bodes well for the future of the country among whose people it exists.

WE have received a copy of a letter from Prof. Hayden, United States geologist, to his Government, asking a further appropriation of 100,000 dols. for the purpose of continuing the geological survey of the territories of the United States during the approaching season. His request is at once granted. For the coming season, the field of labour of the survey is to be

transferred to the eastern portion of the Rocky Mountain Range, in Colorado, and New Mexico.

General Banks has introduced into the U. S. House of Representatives a resolution instructing the Secretary of the Navy to make an examination and survey of that section of the American isthmus which lies between Valencia Point and the Changenola River, on the Atlantic side, and the Boca Chica, the Rio Pedrigal, and the upper part of Golfo Dolce, on the Pacific side. This is to include an examination of the intervening country, of the two cordilleras, and exploration of the courses of the rivers from their outlets to their sources, within the above limits, for the purpose of ascertaining the possibility of such a connection as may be feasible for the construction of an inter-oceanic canal.

Miss Hannah Brakenbury has, among other large legacies, left 12,500*l.* to the Owens College, Manchester, and 9,000*l.* to Durham University.

We learn from the *Times of India* that Mr. Pogson, the Government Astronomer of Madras, has written a long letter to the local Government, suggesting that some special arrangements should be made for observations of the Transit of Venus in December 1874, in Northern India, independently of the Madras Observatory. The letter has been forwarded to the Government of India for consideration.

Les Mondes says that M. Calombel, Procureur-Général of Missions in China, after careful inquiry, gives it as his opinion that Shanghai is one of the most favourable spots for observing the forthcoming transit of Venus. The climate there is somewhat moist, but the month of December is in general very fine; and *Les Mondes* says that without doubt Shanghai will be the scene of M. Janssen's "third glorious campaign." Nankin is also a favourable station, but the inhabitants are not yet sufficiently accustomed to strangers, and the presence there of a scientific expedition might lead to a popular riot.

The Chinese take a curious method to prevent their pigeons from being attacked by birds of prey while circling over the cities or moving from place to place. This consists in the employment of small, short cylinders of bamboo, arranged so as to form a whistle or reed pipe, in groups of three or four, or more. These are attached to the back of the bird, and so adjusted that as it flies through the air a very sharp sound is produced. Varying lengths of the bamboo give variety of tones to this instrument; and when a large number of birds are flying together in a single flock, as is very frequently the case, the sound produced by them is distinctly audible for a great distance. It is said that rapacious birds are effectively repelled by this precaution, so that the pigeons make their flights with perfect safety from one point to another. Varnish is used for coating these bamboo whistles to protect them from moisture This practice is said to have been in vogue among the Chinese for a great many years.

The temperature of February of this year has shown some very curious peculiarities, and a marked contrast to that of the earlier part of the winter, as may be seen from Mr. Glaisher's tables of observations at Blackheath, published weekly in the *Gardener's Chronicle*. While, during the whole of the three preceding months there were only twelve frosty nights, with the temperature of the twenty-four hours almost uniformly above the average of the last fifty years, the thermometer fell below the freezing point in eighteen nights in February, and the temperature was below the average on every day except two, the total depression for the month being 4°·3 Fahr. The records of very few winters will show so high a minimum as 25°·0 Fahr., the lowest temperature of the past winter at Blackheatb, which occurred on February 24 and 25, the thermometer falling below 30°·0 on only seventeen nights during the whole winter. Since March 2 the temperature has been again uniformly above the mean.

A very important extension of the work of the U.S. signal-office, as far as its system of weather telegraphy is concerned, is about to go into operation. It is proposed to call the post-offices of the country into requisition as intermediate agents for disseminating weather intelligence, for which purpose the territory east of the Mississippi has been divided into districts of about two hundred miles in extent each way, and each having a point of distribution near its centre, to which the "probabilities" will be telegraphed from Washington, and from which two copies of the report are to be sent to all post offices within the district which can be reached by mail as early as six o'clock P.M. each day. It is well known that country post-offices are the centres of intelligence to rural districts, and in order to afford the farmers in the community, especially, an opportunity of profiting by this information, postmasters receiving these despatches are to place a copy as soon as furnished in a conspicuous situation, where the public can see and read it.

Apropos of the correspondence going on in our columns on "Inherited Instinct," we take the following from the *Evening Standard* of March 8, though it would have been more satisfactory had the *Standard* named its authority for the statement:—During a recent gale the brig *Blue Jacket*, of West Hartlepool, from Rouen to Shields, was abandoned off Flamborough Head. The crew were taken off, but a cat was left on board. This cat had been given as a kitten to the captain twelve months ago by a lady named Mowbray, living at West Hartlepool, and had never been ashore since that time. On Wednesday last the cat made its appearance at Mrs. Mowbray's house, having swum ashore from the wreck, and travelled thence on foot. It was in a very emaciated condition.

Dr. Elsner, of Berlin, has found that iron is volatilisable at a temperature of at least 3000° centigrade. He experimented with a small piece at this heat, and on uncovering the crucible, distinguished small needles of crystallised iron, says *Les Mondes*.

We are glad to note that *Ocean Highways* has been so successful that next month it is to be considerably increased in bulk, as also in price, the size of the page being at the same time, wisely, we think, somewhat reduced. It is to be hereafter published by Messrs. Trübner.

The Japanese Government proposes to have an institution for the study of practical engineering, and have instructed their agents to procure a set of machinery and tools similar in all respects to that which the Crystal Palace Company last autumn constructed, for the purposes of their admirable school for practical engineering, under the supervision of Prof. Wilson, as Principal.

The additions to the Zoological Society's Gardens during the last week include a puff adder (*Vipera arietans*), a horse-shoe snake (*Zamenis hippocrepis*), and a lacertive snake (*Cælopeltis lacertina*) from Morocco, presented by Sir John Drummond-Hay, K.C.B.; a Rose Hill parakeet (*Platycercus eximius*), from N. S. Wales, presented by Mrs. Hewett; two Moorish tortoises (*Testudo mauritanica*), and three Spanish terrapins (*Clemmys leprosa*), from Algeria, presented by Mr. E. C. Taylor; a crested porcupine (*Hyrtrix cristata*), born in the gardens; a Malayan bear (*Ursus malayanus*), deposited; a pig-tailed monkey (*Macacus nemestrinus*), from Java; a white-cheeked monkey (*Cibus lunatus*), from Brazil; a talapoin monkey (*Cercopithecus talapoin*), and a pluto monkey (*C. pluto*), from West Africa; a Bonelli's eagle (*Aquila bonellii*), from Morocco; two canary finches (*Serinus canarius*), from the Canary Islands; and an Iceland falcon (*Falco islandus*); all purchased.

SCIENTIFIC SERIALS

THE *American Naturalist* for February, among others, contains an article by Dr. Gill on "The Limits of the Class of Fishes," in which he endeavours to modify their generally accepted classification by dividing them up into two classes and three sub-classes, of equal significance with the reptiles and birds. The names he proposes are (1) Pisces; (2) Marsipobranchii; and (3) Leptocardii, which sufficiently indicate the genera he includes in each class. Such an amount of division we think excessive, and it would undoubtedly necessitate the removal of the crocodiles from the reptilia, among other changes. Mr. A. S. Packard gives an account of one of the beaks of a cuttle-fish, probably *Architeuthis dux*, which is four and a half inches long; he also describes other colossal specimens. There is a paper by Prof. Jordan on the colours of vegetation, one by Dr. Abbott on the habits of certain crawfish, and another by Dr. Foster on the pottery of the mound-builders, which is fully illustrated.

THE Munich *Zeitschrift für Biologie*, Bd. 8, Heft 4, contains the following papers of purely medical interest: on the occurrence of enteric fever in the Bavarian army, by Dr. Port, with charts of the mortality in the different barracks and of the amount of subsoil water; On the present state of the cholera problem, by Prof. von Pettenkofer; and on the processes of decomposition which result from venesection, by Dr. J. Bauer.

Schriften der Naturforschenden Gesellschaft in Danzig, New Series, vol. 3, Part I. The first paper in this publication of the Danzig Society is a contribution to primitive German history by Dr. Lissaicer of Danzig, being a very careful and elaborate monograph on some skulls found at Meisterswalde and Krissau, a short distance from Danzig. The paper is accompanied by some capitally executed photographs of the skulls. The next paper is also a contribution to the history of the early inhabitants of Pomerania, being a description by Herr Kasiski of the numerous and varied contents of some of the ancient graves which abound in the district around the village of Persanzig, on the river Persante, a short distance west of Neustettin. The district abounds with material for the archæologist. The paper is accompanied with numerous illustrations of the contents of the graves. The next paper is a long one by Dr. C. J. H. Lampe, of Danzig, on the Movement of Water in pipes, accompanied by some calculations as to the pressure and speed of the water in the pipes by which Danzig is now supplied with water from a considerable distance. This paper is also illustrated, as is also the last one, which is the fifth part of A. Menge's Catalogue of Prussian Spiders.

Der Zoologische Garten (Frankfurt a. M.), January 1873, contains an excellent article, with maps in illustration, of the geographical distribution of the Birds of Paradise, with which are included *Epimachus* and Ptiloris. There is also an article by Dr. H. Dorner on the tongue of the Ka-ka Parrot (*Nestor meridionalis*), in which he shows clearly that in structure it presents none of the characters of the *Trichoglossinæ*, and in other points his results quite agree with those read before the Zoological Society of London in June last, although he, following Dr. Finsch, does not feel disposed to remove this parrot from among those with trichoglossal tongues, because of a supposed similarity in their beaks, which we find it difficult to appreciate, the Ka-ka 's being black and ribbed, whilst that of Lorius is smooth and with an orange tint. There is not the least doubt that, now it has been doubly demonstrated that their tongues are not similarly constructed, there is not any good reason for associating the Nestors with the Lories.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 6.—"On the Vapour-density of potassium."—Preliminary notice. By James Dewar and William Dittmar.

The results of their observations conclusively show that the density of potassium-vapour, as produced in the process described, cannot exceed 45 times that of hydrogen, and that therefore the molecule of potassium consists of *two atoms* (K_2).

"On New Sources of Ethyl- and Methyl-Aniline." By John Spiller, F.C.S.

"On a new genus of Amphipod Crustaceans. By Rudolph von Willemoes-Suhm, Ph.D., Naturalist to the *Challenger* exploring expedition.

In lat. 35° 47', long. 8° 23', off Cape St. Vincent, the traw was sent down to a depth of 1090 fathoms on the 28th of Januaryl and brought up among other very interesting things a larg, transparent Amphipod with enormous facetted eyes. The animale evidently hitherto unknown, will be the type of a new genus, having the following characters:—

THAUMOPS, nov. gen.

Caput oblongum, inflatum, oculis maximis superiorem capitis partem tegentibus. Segmenta thoracica 6, abdominalia 5. Antennarum in feminis par unum, maxillarum par unum, pedum paria duo minima maxillarum locum tenentia. Mandibulæ nullæ. Pedes thoracici 5, abdominales 3 in quoque latere. Appendices caudales 4. Gangliorum pectoralium paria 5, abdominalium 3.

T. pellucida, n. sp.

Corpus longitudine 14 mm., latitudine 21 mm., pellucidum.

It could not be made out whether *T. pellucida* inhabits the deep sea, or whether it is, like *Phronima*, a pelagic animal, having been caught by the trawl only as the latter came up from the depth.

Geological Society, February 26.—Prof. Ramsay, F.R.S., vice-president, in the chair.—The following communications were read:—"On the Jurassic Rocks of Skye and Raasay," by Dr. James Bryce. In this paper the author described numerous sections of Jurassic rocks exposed chiefly in the sea-cliffs of Skye and Raasay, indicating the presence in those islands of a complete series of beds ascending from the Lower Lias to the middle of the Middle Oolite. He noticed the occurrence in these sections of fossils belonging to the zones of *Ammonites angulatus* and *A. Bucklandi* in the Lower Lias, to the zones of *A. Jamesoni*, *A. capricornus*, *A. margaritatus*, and *A. spinatus* in the Middle Lias, of Upper Lias fossils, including *Ammonites communis*, *falcifer*, *heterophyllus*, and *bifrons* and of others indicating beds belonging to the Inferior Oolite and Cornbrash, and to the Oxford Clay. The Loch Staffin beds were described as an estuarine series, nearly approaching the Oxford Clay in geological age, and including a bed almost entirely made up of shells of *Ostrea hebridica*. The whole series of Jurassic rocks in these islands reposes on the Toridon sandstone of Cambrian age; and the author discussed the question whether or not the intervening beds have ever existed in this locality, and came to the conclusion that they probably existed, and have been swept away by denudation. He remarked further upon the resemblance in lithological characters of the beds described with the corresponding deposits elsewhere in Britain. The traprocks intruded between the Jurassic deposits he regarded as of post-oolitic date.—"Observations on the more remarkable Boulders of the North-West of England and the Welsh Borders," by Mr. D. Mackintosh. In this paper the author described the situation and indicated the probable origin of many of the more striking known boulders in Westmoreland, Cumberland, Lancashire, Cheshire, and on the borders of Wales. The northern boulders seem to have orignated chiefly from Wastdale Crag, Criffel, Ennerdale, and Eskdale; those of Cheshire chiefly from the Lake District and South of Scotland; and many of those on the Welsh borders from the mountains of Wales. Many of the boulders noticed by the author exhibit glacial striæ. The author also especially referred to the occurrence of boulders at high levels.

Linnæan Society, March 6.—Mr. Bentham made some observations on the homology of the perigynium or utricle of the female flowers of Carex and Uncinia, with a view to calling to the disputed points in question the attention of botanists used to microscopical investigation, who may have the opportunity of examining living specimens in the earliest stages of flowering. Two principal explanations of the homology of the perigynium of Carex have been given. Brown, relying upon its being composed of two squamæ, considered that it represents a perianth, and Payer and Schleiden have adopted the same view, after an examination of its appearance at a very early stage. Kunth, on the contrary, believed it to be formed of a single scale, and to be an ordinary glume subtending the female flower on a secondary axis, of which the seta of many species of Carex, and of

all the species of Uncinia, is the continuation. If the perigynium is really formed of a single scale, Kunth's view is very plausible, but the two keels or principal nerves, which in most species end in two points or lobes, are strong evidences of its double nature. Kunth explains that circumstance by the suppression of the central nerve or keel owing to pressure, of which, however, there is no appearance in any species examined. Payer states also positively that the two are distinct at an early stage, and unite as they grow up; but implicit reliance is not always to be placed upon his having always clearly seen the minute microscopic and obscure protuberances he delineates. Schleiden delineates the two parts of the perigynium and the seta as forming three parts of one whole; but his drawing is not to be depended upon, as he places them in a wrong position with relation to the axis and the subtending glume. Kunth confirms his views by a comparison with the palea and occasional seta of Gramineæ, but here the position of the two parts in the two orders is by no means homologous. Independently of the relation to the other parts of the flower, the seta or prolonged axis in Gramineæ is outside the paleæ, in Carex inside the perigynium. A stronger confirmation is taken from two South African species of Schœnoxiphium (not generically distinct from Carex) in which the seta occasionally bears a spike of male flowers. This spike appears to be sterile, and may be a case of prolification, but requires further investigation. If it be a normal spike, we must conclude the perigynium or subtending glume to be formed of one scale; for two opposite scales at the base of an alternate inflorescence is a derangement of the ordinary course of change from the alternative vegetative organs to the opposite or whorled floral organs, which is believed to have no example at least in Monocotyledons. If the perigynium is formed of two scales they must belong to the floral whorls. They are not subtending bracts analogous to the two free bracts of Diplacrum, or the united ones of Hoppia, for in both those cases the female flowers are terminal without any other subtending glume, and in Carex the female flower is lateral, and the perigynium is within one outer subtending glume. That they are two out of three parts of a real perianth is rendered improbable by their great development in one sex in an order where it is in all other genera suppressed or rudimentary, and without any trace of it in the other sex. The only remaining supposition is that the perigynium and seta represent the stamens of the male flowers, and are therefore in fact staminodia. The position with relation to the axis and subtending glume is the same, and although they are very different in form and texture, that difference is much diminished in *Uncinia longifolia* where the dilated filaments of the males assume the aspect nearly of the perigynium of the females. The lobes of the perigynium in *Carex subulata*, and occasionally in some Unciniæ, have the look of the seta of Uncinia, and in one instance that seta bore a perfect anther. Brown confirmed his view of the perianth-nature of the perigynium by a specimen of *Carex acuta* with stamens within the perigynium. An examination of beautiful specimens of this form of *Carex acuta*, gathered by Mr. Spruce in Yorkshire, shows, from the position and structure of the stamens bearing perigynia, that they are altered female flowers in which more or less imperfect stamens replace the carpellary leaves of which the pistil is formed. If this homology of the perigynium with the andrœcium of the male flower is thought plausible, it is still doubtful, and the doubt can only be solved by a careful repetition of Payer's observations, and a repeated study of the anomalies of Schœnoxiphium, and of those species of Carex in which the seta is variously developed, many of the forms delineated in the late Dr. Booth's splendid illustrations of the genus requiring a special study on the specimens themselves.

Zoological Society, March 4.—Mr. John Gould, F.R.S., V.P., in the chair.—Mr. Edwin Ward exhibited the original leg-bones of *Dinornis maximus*, from Glenmark Swamp, near Christchurch, New Zealand, described by Prof. Owen in the Society's "Transactions," belonging to Col. Michael.—A communication was read from the Rev. O. P. Cambridge on the spiders of St. Helena, founded on the collections made in that island by Mr. Melliss. The total number of known spiders of St. Helena was stated to be forty, of which eleven were now described for the first time. The species were mostly European in form.—A communication was read from Dr. John Anderson, F.Z.S., Curator of the Indian Museum, Calcutta, on the species and dentition of the Southern Asiatic Shrews, preliminary to a proposed monograph of the group.—A communication was read from Mr. M. R. Butler, being the description of a remarkable new species of butterfly, of the genus *Tanaecia*, from Penang.—Messrs. P. L. Sclater and O. Salvin read a paper on the birds of Eastern Peru, with notes on the habits of the birds by Mr. E. Bartlett. The total number of species hitherto recorded as met with in the district was stated to be 473, of which 108 were unknown elsewhere.—A communication was read from Surgeon-Major Francis Day on some new or imperfectly known fishes of India.—A communication was read from Mr. G. E. Dobson, M.B., on secondary sexual characters in the Chiroptera. Mr. Dobson pointed out that, contrary to what Mr. Darwin had believed to be the case, special structural characters existed in the males of species of the genera *Phyllorhina Taphozous*, and other genera of bats.

Anthropological Institute, Feb. 18.—Prof. Busk, F.R.S., president, in the chair. Sir John Lubbock, Bart. exhibited two heads of Macas Indians, and contributed a note of the mode of their preparation. Mr. W. Topley read a paper "On the Relation of Parish Boundaries in the south-east of England to Great Physical Features, particularly to the Chalk Escarpment."

March 4.—Prof. Busk, F.R.S., president, in the chair.—A paper was read by Dr. A. Campbell "On the Looshais," a people inhabiting the hill district of Chittagong. They are fairer in complexion than the people of the plains, and their features resemble those of the Malays rather than the Tartar-like people of Mumpore. They have no distinction of caste; marriage is a civil contract, dissolvable at the will of both husband and wife. The men live by hunting, whilst the women are engaged in household work.—Sir Duncan Gibb read a paper on "Stone Implements and Pottery from Canada." After describing a collection of arrow and spear heads, some hatchets, and pottery collected by himself in various parts of Canada, he considered the first two as the most ancient implements found in that country, for reasons which he gave, and placed the period of their use at about 200 B.C., although he saw no reason why they might not have been employed 4,000 years ago.—Mr. Hodder M. Westropp contributed a short paper on "The Ventnor Flints," descriptive of fragments of flint and other stone, bearing resemblances to the true arrow-heads and implements of ancient manufacture; and it was shown that the specimens exhibited were wanting in the bulb of percussion and the chipping at the edge which characterised the genuine articles.—The President described an Australian skeleton from the Murray River, which had been sent to the museum of the institute by Dr. Robert Peel, of Adelaide. It was announced that further committees had been appointed for Physical Characters of Mankind; Priscan Archæology; and Descriptive Ethnography.

Chemical Society, March 6.—Dr. Gladstone, F.R.S., vice-president, in the chair. The following communications were read: "On the action of hydrochloric acid on codeine," by Dr. C. R. A. Wright, being a continuation in the codeine series of the author's former researches on morphine. "On new processes for mercury estimation with some observations on mercury salts," by J. B. Hannay. "On a method of estimating nitric acid," by T. E. Thorpe, F.R.S.E., the process depending on the ease with which nitric acid is converted into ammonia by the copper-zinc couple of Messrs. Gladstone and Tribe. "Note on a reaction of the acetates upon lead salts with remarks on the solubility of lead chloride," by F. Field, F.R.S. "Observations on the nature of the black deposit in the copper-zinc couple," by J. H. Gladstone, F.R.S. and A. Tribe, F.C.S. "On an air-bath of constant temperature between 100° and 200° C.," by Dr. H. Sprengel. This consists of a bath similar to the ordinary chemical hot-water oven but made of sheet-lead and filled with dilute sulphuric acid of such a strength as to boil at the desired temperature.

Entomological Society, Feb. 17.—Prof. Westwood, president, in the chair.—Mr. Bond exhibited bred specimens of *Acronycta tridens* and *A. Psi*, showing the differences between the two species.—Mr. Müller exhibited some spiral cases of a species of *Psyche*, and also the egg-case of a species of *Mantis*, both sent from Calcutta by Mr. James Rothney.—Prof. Westwood exhibited two dipterous larvæ preserved in spirits, discharged by a woman in a clot of phlegm, which were probably larvæ of *Psila rosæ*, swallowed with raw carrots. After they had been immersed in spirits for three or four days he took them out for examination, and was surprised to find that they were still alive. He also showed drawings of vine-stems, with excrescences caused by a beetle (*Otiorhynchus*).—Mr. H. W. Bates read a paper on the geodephagous beetles of Japan, col-

lected by Mr. George Lewis.—Mr. Müller read a list of entomological works and papers, no notice of which was to be found in Dr. Hagen's "Bibliotheca Entomologica."—Mr. F. Smith read some remarks by Prof. Siebold, on the salivary organs of the honey-bee.

March 3.—Prof. Westwood, president, in the chair. Mr. Vaughan exhibited a box containing about 200 specimens of Japanese *Lepidoptera* collected by Mr. Henry Pryer, near Yokohama.—Mr. T. Smith exhibited insects bearing a remarkable resemblance to each other, although belonging to different orders. *Euglossa dimidiata*, a bee, had a striking resemblance to a species of the Dipterous Genus *Asilus* from South America. Also *Abispa splendida*, one of the *Vespidæ*, resembled an insect of the Dipterous genus *Laphria*: both from N. Holland. Also a bee of the genus *Megachile* resembled an *Asilus*. The two last-mentioned resembled each other, not only in general appearance, but the *Asilus* was also furnished on the under side with a pollen brush, in the same manner as in *Megachile*, although it was not apparent for what purpose the insect required it. The president remarked that when he was at Ancona he observed several insects of the genus *Osmia* and *Megachile* extracting pollen from black poppies, and on the sandy shore he noticed the same insects collecting the sand. He therefore concluded that the pollen brushes were used, not only for collecting the pollen, but also for carrying the grains of sand to their nests. It was probable, therefore, that the *Asilidæ* that were furnished with brushes might use them for a similar purpose. Mr. Champion exhibited *Bagous brevis*, taken in this country for the first time by Dr. Power.—Mr. Müller directed attention to an article in the *Petites Nouvelles* explaining a method of obtaining silk from cocoons which had been eaten through by the insects—and that the silk so obtained from the damaged cocoons was equal in quality to that obtained from the perfect cocoons.

Royal Horticultural Society, March 5.—Scientific Committee.—J. D. Hooker, M.D., C.B., F.R.S., in the chair. A note was read from Dr. Boswell Syme on the intra-palear fertilisation of wheat. He found that the anthers are *empty* when they are extended, and that the stigmas are never extended beyond the pales at all.—Mr. A. W. Bennett read an abstract of a paper by Hildebrand, on the same subject.—The Rev. M. T. Berkeley exhibited specimens of a fungus, *Cladosporium herbarum*, from the inner surface of the shell of a boiled egg.—General Meeting.—W. Wilson Saunders, F.R.S., in the chair. Prof. Thiselton Dyer made some remarks on a cone of *Araucaria Bidwilli* from the tree in the temperate house at Kew, on specimens of *Dendrobium Hillii* and *Clematis indivisa*, a fine species from New Zealand, and also on *Amorphophallus Rivieri*, a remarkable Aroid with inflorescence, shown by Mr. Bull. It had been introduced by the French into the Jardin d'Essai at Algiers, from Cochin China.

Royal Microscopical Society, March 5.—Chas. Brooke, F.R.S., president, in the chair. Mr. E. J. Gayer contributed some further notes on the micro-spectroscope and microscope, in continuation of his paper upon the same subject, read at the December meeting of the Society.—A paper by Dr. Maddox, on a minute plant found in an incrustation of carbonate of lime, was also read to the meeting, and was illustrated by drawings and prepared specimens exhibited under the microscope, by Mr. Reeves.—The secretary stated, with reference to some crystals shown at the previous meeting, obtained from the condensed vapour of coke, that they had been examined by Mr. Bell, and found to consist chiefly of protosulphate of iron.—A new metallic chimney for microscope lamps was introduced by Mr. Wenham, its merits being explained by the secretary, and discussed by the meeting.

CAMBRIDGE

Philosophical Society, Feb. 3.—Professor Humphry, president, in the chair. It was decided to admit as associates residents in Cambridge and the neighbourhood, not being graduates. Associates to be elected for a period of three years, and if not then graduates to be eligible for re-election. The president in an eloquent address dwelt upon the loss which the Society had sustained by the death of Prof. Sedgwick, its founder and ever-ardent supporter. The following communications were made by Prof. Clerk Maxwell: "On the proof of the equations of motion of a connected system," and "On a problem in the calculus of variations in which the solution is discontinuous."

Feb. 17.—The following communications were made by Mr. Paley "On the name *Odusseus* signifying 'setting sun,' and the Odyssey as a solar myth." This showed that the name was most probably connected with δυόμενος ἥλιος (setting sun) and that the details of the Odyssey were easily interpreted as a solar myth, describing the journey of the sun to the west and his return after many struggles and adventures to his ever-young bride in the east, Penelope the spinstress, *i.e.* the cloud-weaver.—"On the identity of the modern Hindu with the ancient Greek ship." A model of the former (Bengalee) was exhibited and the close coincidence in build, rig, and tackling was pointed out; and several difficulties in the allusions of classic authors to the parts of a ship were thus explained.

MANCHESTER

Literary and Philosophical Society, Feb. 18.—E. W. Binney, F.R.S., vice-president, in the chair. Dr. Joule, F.R.S., gave some further account of the improvements he had made in his air-exhausting apparatus (See NATURE, vol. vii. p. 296).

"Notes on a supposed Glacial Action in the Deposition of Hematite Iron Ores in the Furness District," by William Brockbank, F.G.S. The hematite iron ore deposits in the Furness district are of two very different varieties—(1) Those filling hollows in the limestone, covered only by the post tertiary gravels and clays, and (2) Those occurring in the carboniferous limestone in veins, and large irregular cavities or "pockets." The superficial deposits (1) are more especially the subject of the present communication, as they afford, in the writer's opinion, undoubted evidence of glacial action, and of the mode in which the iron ore has been transported by its agency.

"The Results of the Settle Cave Exploration," by W. Boyd Dawkins, F.R.S. Since the results of the exploration of the Settle Caves were brought before the British Association at Liverpool, in 1870, considerable progress has been made in the further investigation of the remarkable contents of the Victoria Cavern. Up to that time our researches had revealed, perhaps, the most remarkable collection of enamelled jewellery which had ever been discovered in one spot, along with broken bones of animals and the implements of everyday life, which afforded a pointed contrast to the culture implied by the workmanship of the articles of luxury. The Roman coins, and the style of workmanship of the implements, pointed out that the cave was occupied during the troublous times when the Roman Empire was being dismembered by the invading barbarians, and when Britain, stripped of the Roman legions, was falling a prey either to the Picts and Scots on the one hand, or to the Jutes, Angles, and Saxons on the other. If we stretch the limits of the occupation to the latest, they cannot be held to extend nearer to our own times than the Northumbrian conquest of Elmet (or kingdom of Leeds and Bradford) by Eadwine, in the year A.D. 616, that was preceded in 607 by the march of Æthelfrith on Chester, and the great battle near that Roman fort, celebrated in song for the defeat of the British and the slaying of the monks of Bangor. At that time the Northumbrian arms were first seen on the shores of the Irish Channel, and the fragment of Roman Britain—which had extended on the western part of our island, from the estuary of the Severn uninterruptedly, through Derbyshire and Lancashire into Cumberland—was divided, never again to be united. The Roman civilisation, which had up to that time been maintained in that district, disappeared, and was replaced by the civilisation which we know as English. The traces, therefore, of Romano-Celtic ornaments and implements from the Victoria Cave must be assigned to the period before the English conquest, before the Northumbrians conquered West Yorkshire and Mid-Lancashire. Underneath the stratum containing the Romano-Celtic or Brit-Welsh articles, at the entrance of the cave, there was a thickness of about six feet of angular stones, and at the bottom of this a bone harpoon or fish-spear, a bone bead, and a few broken bones of bear, red deer, and a small short-horned ox prove that in still earlier times the cave had been inhabited by man. A few flint flakes probably imply that these remains are to be referred rather to the Neolithic age than to that of Bronze. Below this was a layer of stiff clay, into which the committee sank two shafts, respectively of twelve and twenty-five feet deep, without arriving at the bottom. They have, however, at last penetrated it, and have broken into an ossiferous bed, full of the remains of extinct animals, similar to those which have been discovered at Kirkdale and elsewhere; consisting of the cave-bear, cave hyæna, woolly rhinoceros, mammoth, bison, reindeer, and horse. The bottom has not been reached, and the area exposed is so small that it is impossible to say whether man was

living in the cave at this time or not. The clay immediately above it is considered, both by Mr. Boyd Dawkins and Mr. Tiddeman, to be of glacial origin, and in that case this cave is the only one in Great Britain which has offered clear proof that this group of animals was living in the country before the glacial age. It may be that the remains of man may be discovered here, as in the caves of Wookey Hole, Kent's Hole, and Brixham; but this problem can only be solved by an exploration on a larger scale, which the committee hope to be able to carry on by the aid of further subscriptions, and which the British Association has thought sufficiently important to aid by a grant of 50*l.* The problem which they are attempting to solve, is not merely of local interest, but one which is worthy of the aid of all who care for the advancement of knowledge. "The explorations of the Victoria Cave," writes Mr. Tiddeman, "carry with them more than common interest, from the probability of making out in this district the relation of the older cave mammals (and perhaps of man) to the Glacial period. The complete absence of this fauna from the river gravels and other Post-Glacial deposits of this district, taken with the former existence of a great development of ice over the northern counties, renders it highly probable that the latter was the agent which removed their remains from all parts of the country to which it had access, leaving them only in sheltered caves. In this cave we find, above the beds containing the older fauna, a deposit of laminated clay of great thickness, differing so much from the cave-earth above and below it as to point to distinct physical conditions for its origin. Clay in all respects similar, but containing scratched stones, has been found intercalated with true glacial beds in the neighbourhood, thus rendering the glacial origin of that in the cave also highly probable. Moreover, at the back of a great thickness of talus at the entrance glaciated boulders have been found, resting on the edges of the beds of lower cave-earth containing the older mammals. All points considered, there is strong cumulative evidence pointing to the formation of the lower cave-earth at times at any rate prior to the close of the Glacial period and probably earlier. It is to be hoped that further investigations may settle these and other most important questions." The objects found in the Victoria Cave will not be removed from the county, but will be placed in a museum attached to the Grammar School at Giggleswick.

DUBLIN

Royal Irish Academy, Jan. 13.—The Rev. Prof. Jellett, president, in the chair. Mr. B. O'Looney read a paper on the contents of the Book of Leinster.—Mr. W. H. Bailey, F.G.S., read a paper on a new species of Labyrinthodont Amphibian from Jarrow Colliery, Co. of Kilkenny. This species the author said was, he believed, identical with the species referred to in Messrs. Huxley and Perceval Wright's paper on fossil vertebrata from County Kilkenny, as being "a large amphibian, closely allied to, if not identical with, the *Anthracosaurus* of the Scotch coalfield," and of which he had been shown some very fine specimens in the British Museum. He proposed to call this species *A. edgii.*

Jan. 27.—Rev. Prof. Jellett, president, in the chair. Prof. E. Perceval Wright read a report on *Hyalonema mirabilis.*

Feb. 24.—Lord Talbot de Malahide, vice-president, in the chair. The Rev. Prof. Jellett, president, read a paper on sugar-beet grown in Ireland in 1872, in which he stated that, having frequently heard it said that Ireland was not a country in which the beetroot could be successfully cultivated, he had been led to make several experiments on the subject. The results in 1871, which was a dry and sunny year, and those he had obtained in 1872, which was one of the wettest and coldest, presented very little difference. He had been furnished last year from the Albert Model Farm, Glasnevin, with four specimens of sugar-beet, in the growth of one of which the manure used was common salt; in the second case, sulphate of potash; in the third case no manure was used; and in the fourth instance, sulphate of ammonia. He had by optical experiment determined with accuracy that in the first case there was a yield of 79·99 per cent. of water and 12·72 per cent. of sugar; in the second, 80·27 of water and 13·18 of sugar; in the third, 80·60 water and 12·42 sugar; and in the last, 80·52 water and 11·85 sugar. The average of these was 80·34 per cent. of water and 12·54 per cent. of sugar. The amount of sugar thus found to be contained in the Irish-grown beet was quite equal to that in beet grown in Germany, Belgium, and France, and proved Ireland to be a country in which sugar-beet might be cultivated with advantage.

EDINBURGH

Scottish Meteorological Society, Jan. 30, half-yearly meeting.—Mr. Milne Holme in the chair.—Mr. Buchan made a statement with reference to the remarkable weather which has prevailed in this country during the past year. The specialty of that year's weather was, he said, its rainfall. The mean rainfall for sixteen years of the whole of Scotland, as indicated by the average of 55 stations, was 39, 1-5th in. The year 1857 was a dry year, its rainfall being 8 in. less than the mean; 1858 fell below the mean by 5 in.; 1861 was 6 in. above the mean; but the rainfall of last year ran up to 15 in. above the mean, the average rainfall of the whole of Scotland during that year being 54 in. This rainfall was 38 per cent. above the mean, and there was nothing approaching it in any of the previous sixteen years. This enormous rainfall was very unequally distributed over the country. He had constructed a map of Scotland based upon the returns from 200 stations. In this map a blue line passing round the north of the Shetland Islands, cutting off the north-west fringe of Caithness and Sutherland, and then bending down southward, but returning northward again so as to pass round the north of the Hebrides, cut off a part of Scotland within which there was last year less rain than usual. Between this and another line which stretched from Shetland, took in part of Orkney, curved down round Islay, and took off a part of the Hebrides, was included a portion of the country where the rainfall did not amount to 25 per cent. above the average. Then suppose a line beginning about Peterhead, curving round so as to include Elgin, and following very closely the east watershed of Scotland, all places to the east of that line were found to have had at least half more rain than usual. Further, the country about Aberdeen and a good part of East Lothian and Berwickshire had an excess above the average to the extent of 75 per cent. Not only so, but taking some of the individual stations, it appeared that Culross, the highest the society had, stood 93 per cent. above the average; Thurston, near Dunbar, 88 per cent. above the average of thirty-two years; Jedburgh, 84 per cent. above the average; and other places fully 80 per cent. above the average. These figures showed a very remarkable distribution of the rainfall for the last year; he thought the records of meteorology had nothing like it. In Castle Gordon, Banffshire, the rainfall of last year was $5\frac{3}{4}$ in. above any rainfall in the previous ninety years. At Edinburgh there were sixty years' observations to go back upon, and last year's rainfall exceeded to the extent of over 4 in. any recorded within that period. With reference to the distribution of rain over the year, the fall in January was greatly in excess of the average, and it only fell below the average in April, every other month showing an excess. On the east side of Scotland, taken as a whole, every month of last year was above the average—an unprecedented fact, he thought, in Scottish meteorology. In the west of Scotland, one month was decidedly under the average, and another month stood at the average, every other month being above the average. June was a very wet month in the west. August was a drier month. September appeared rather wet, but that was due to the greater rainfall in the south, for to the north of Islay the rainfall of that month was very much under the average. As to temperature, for the first four months it was above the average; in May and September very much under the average; June about the average; July above the average, and so on; so that in this respect the year was not on the whole a very bad one. With regard to barometric pressure, he had worked out the mean of 55 stations, and it appeared that for every month, except July and August, the pressure of Scotland was under the average. Northerly, north-easterly, easterly, south-easterly, and southerly winds were above the average; and the distribution of rain was the representative of that fact, a great proportion of the rain that fell having been brought by easterly winds. The atmospheric pressure in Iceland was above the average in every month except January, and during the whole year the pressure in that island was much higher than with us. In the north of Norway the pressure was still higher than in Iceland, and showed a more irregular curve. Following out this point in other parts of Europe, it appeared that in England the pressure was under the average; in Guernsey it was under the average each month, and a similar state of matters prevailed in Ireland, France, Switzerland, Germany, and Austria. On the other hand, in Iceland, the northern part of Norway and Sweden, in Russia, at Constantinople, at Athens, at Moscow, in the north of Africa, and in Spain, pressure was above the average, and the rainfall for the year less than the average. So far as the facts

went it did not seem to him that the rainfall of the whole globe during last year was larger than usual. In the West Indies it was a very dry year up to the beginning of November. In the United States, at least till the end of September, it was drier than usual, and in the north of Europe much drier than usual. In short it seemed that the rainfall of the year instead of being more evenly distributed, as usually happened, had been more concentrated in Scotland, England, France, Italy, south of Norway, Germany, and Austria.

Paris

Academy of Sciences, March 3.—M. de Quatrefages, president, in the chair.—The following papers were read:—"On the Elliptical Oscillation of Solar Cyclones," by M. Faye. The paper dealt mainly with the mathematical nature of the spots, and the author gave a table in which he showed the exact resemblance which can be traced between the solar and terrestrial cyclones.—"On the Action of the Electric Current on a Mixture of equal volumes of Methene and Carbonic Anhydride," by MM. P. and A. Thenard. The authors find that the silent discharge, when allowed to act on the above mixture, produces a clear, limpid fluid, but that the spark causes an expansion of the gases sometimes accompanied by a deposit of carbon. No analysis of the liquid was given.—"On the Nature and Origin of the Solar Spots," a letter from Father Secchi, who believes that, even admitting M. Faye's cyclones, yet the cause of these must be sought in eruptions. He asserts that he did not say, as M. Faye supposed, that the spots *were* eruptions, but that they were *produced by* cruptions.—The Academy then proceeded to elect a member of the physical section in the place of the late M. Duhamel. M. Berthelot obtained 33 votes, M. Desains 23, and M. Le Roux 4. M. Berthelot was accordingly elected.—A report on a memoir by M. Kretz on the elasticity of moving machines was read.—A paper on the botanical geography of Morocco, by M. F. Cosson, followed; and next came a paper on geodetic operations, by Col. H. Levret, and one on the simultaneity of barometric variations in the high latitudes of either hemisphere, by M. J. A. Broun.—M. B. Renault presented a paper on the fructification and on the structure of the stems of *Annularia* and *Sphenophyllum*.—M. Chasles presented a paper on the trajectories of the points of a straight motion in space, by M. A. Mannheim, and a note on double curves of the sixth order, by M. Ed. Weyer.—M. L. Joulin sent a paper on saline decomposition, a paper relating to the part played by the water used to dissolve a body, when that body is precipitated by means of another.—MM. Troost and Hautefeuille sent a second instalment of their paper on the solution of gases in molten cast-iron. They find that a highly silicious iron scarcely dissolves any hydrogen.—M. Gernez presented another paper on the action of films on supersaturated solutions.—M. Pasteur presented a paper by M. J. Chautard, on the modification of the chlorophyll absorption spectrum, produced by the action of alkalies. The alkalies cause the appearance of a second band in the red.—MM. Houzeau and Renard presented a paper on the use of concentrated ozone in investigations in organic chemistry, and on "ozobenzine." The latter is a gelatinous body produced together with formic and acetic acids by the action of ozone on pure benzine.—Mr. T. L. Phipson sent a note on Anthracenamine.—M. Wurtz presented a second note on the derivatives of Tetrachloride of naphthaline, by M. Grimaux.—This was followed by M. P. Bert's ninth note on the effects of changes of barometric pressure on life. MM. P. Fischer and de Tolin sent a note on the bathymetric exploration of the fosse at Cape Breton, and M. J. Jullien a note on the respiration of the *Psammodroma*.

DIARY

THURSDAY, March 13.

Royal Society, at 8.30.—Note on Supersaturated Saline Solutions: C. Tomlinson.—Visible Direction: Dr. Jago.

Society of Antiquaries, at 8.30.—Excavations in the Troad: Dr. Schliemann.

London Mathematical Society, at 8.—On an Extension of the term *Area* to a closed curve of double curvature or Skew Polygon: R. B. Hayward.—On the Evaluation of a class of Definite Integrals involving Circular Functions in the Numerator, and powers of the Variable only in the Denominator: J. W. L. Glaisher.—Note on Normals and the Surface of Centres of an Algebraical Surface: S. Roberts.

Royal Institution, at 3.—Forces and Motions of the Body: Prof. Rutherford.

FRIDAY, March 14.

Royal Institution, at 9.—Coral Reefs and their Architects: Prof. Allman.

Astronomical Society, at 8.

Quekett Club, at 8.

Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.

SATURDAY, March 15.

Royal Institution, at 3.—On the Philosophy of the Pure Sciences: Prof. W. K. Clifford.

SUNDAY, March 16.

Sunday Lecture Society, at 4.—The Education of Women: Mrs. Fawcett.

MONDAY, March 17.

Entomological Society, at 7.

Asiatic Society, at 3.

London Institution, at 4.—Physical Geography: Prof. Duncan.

Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.

TUESDAY, March 18.

Statistical Society, at 7.45.

Anthropological Society, at 8.—On "Theories regarding Intellect and Instinct," and "The Concurrent Contemporaneous Progress of Renovation and Waste: George Harris.

Zoological Society, at 8.30.—On some Marine Mollusca from Madeira, including a new genus of the *Muricidæ*. Communicated by Mr. Gwyn Jeffreys: R. B. Watson.—On a specimen of *Acanthias vulgaris* and a species of *Galeus*, probably new, taken off Flinder's Island, Bass' Straits: Dr. John Denis Macdonald.—Note on the Gazelles of India and Persia, with description of a new species (*Gazella fuscifrons*): W. T. Blanford.

Royal Institution, at 3.—Forces and Motions of the Body: Prof. Rutherford.

WEDNESDAY, March 19.

Society of Arts, at 8.—On certain improvements in the Manufacture of Printing Types: J. R. Johnson.

Meteorological Society, at 7.—On some results of Meteorological Telegraphy: R. H. Scott.—On the Barometric Depressions of Jan 24, 1872: Wm. Marriott.

Royal College of Surgeons, at 4.—Extinct Mammals: Prof. Flower.

London Institution, at 7.—Travers Course (Lecture I).

THURSDAY, March 20.

Royal Institution, at 3.—The Chemistry of Coal and its Products: A. V. Harcourt.

Chemical Society, at 8.—On Iron and Steel: C. W. Siemens.

Linnean Society, at 8.—On the "Take-all" Corn Disease of Australia: Dr. Mücke.

PAMPHLETS RECEIVED

English.—Report of the Marlborough Natural History Society.—Journal of the Iron and Steel Institute, No. 4.—Quarterly Journal of the Meteorological Society.

American.—Annual Report of the Survey of the Northern and North-Eastern Lakes: C. B. Comstock (Washington).—Movable Torpedoes: Capt. Ericsson.—On a new Sub-Class of Fossil Birds.—On the Gigantic Fossil Mammals of the order Dinocerata: Prof. O. C. Marsh.

Foreign.—Introduction a l'Etude de la Nutrition des Plantes, &c.: E. Morren.—Report of the Proceedings of the Meteorological Conference at Leipzig, 1873.—Cosmos, No. 1.

CONTENTS

THURSDAY, MARCH 20, 1873

PERCEPTION AND INSTINCT IN THE LOWER ANIMALS

THE correspondence in these columns, called forth by the letters of Mr. Darwin and Dr. Huggins (NATURE, Feb. 13), may be counted among the many indications of the growing interest in psychology; while at the same time it furnishes evidence of how far our knowledge of mind is behind most of the other sciences. Of the important points in the valuable letters of Mr. Darwin and Dr. Huggins we shall speak presently. But let us remark first on the minor and distinct question raised by Mr. Wallace. He says: "The power many animals possess to find their way back over a road they have travelled blindfolded (shut up in a basket inside a coach, for example), has generally been considered to be an undoubted case of true instinct. But it seems to me that an animal so circumstanced will have its attention necessarily active, owing to its desire to get out of its confinement, and that by means of its most acute, and only available sense, it will take note of the successive odours of the way, which will leave on its mind a series of images as distinct and prominent as those we should receive by the sense of sight. The recurrence of these odours in their proper inverse order—every house, ditch, field, and village having its own well-marked individuality—would make it an easy matter for the animal in question to follow the identical route back, however many turnings and cross-roads it may have followed." The objections to this hypothesis, to which Prof. Robertson has given his adhesion, are very serious. Let the scent of the dog be ever so acute, it is in many ways ill suited for supplying the kind of guidance required. A hound on the track of a hare has to follow a stream of the same scent. The association here is between the hare and the smell of the hare. Are not the associations of smell all of this kind? Is there any evidence that either in man or beast one smell ever coheres to another so as to render possible a memory of odours apart from the objects that give them forth? We are not very certain about the facts which the theory is put forward to explain; they are, however, better authenticated than is the fundamental assumption involved in the explanation. But, for the sake of argument, let us grant that a dog shut up in a basket can, as the result of a simple experience, link together several thousand smells in an unbroken series; say, the stink of a dung-hill is associated with the odour of sweet hay, this with the scent of a flock of sheep passed on the road, this again with the smell of a railway station to the right, and so on during a journey of sixty or seventy miles. If it be solely by the aid of this memory of smells that the dog is to return to the place whence it was taken, it must needs make haste back. It will be too late if the sheep have changed their position on the road. Especially is it necessary that it should get home while the wind still continues to blow in the same direction, otherwise its landmarks will be all in confusion. One other difficulty: suppose the dog to have got into the fragrance of the hay-field, which is perhaps forty acres in extent, how is it to find the dung-hill at the north-west corner? particularly if the wind be blowing the wrong way. Is it to scour round the ill-defined outskirts of the perfume until it comes on the ill smell of the dung-hill? If we try to conceive in terms of vision (we can make nothing of it from our experiences of smell) such a memory of smells as the dog is supposed capable of acquiring, we must represent to ourselves the sensations of being carried through a series of differently coloured mists, which, while they prevent us from seeing objects, blend and shade into one another. In such a case, though we might remember that the red came after the yellow, how, having got into the red, should we know in what direction the yellow might be found? These are among the difficulties that have not, it appears to us, been sufficiently considered by Mr. Wallace and Prof. Robertson.

But what are the facts to be explained? Such home-journeys of dogs as might, by a stretch of imagination, or perhaps more correctly, want of imagination, seem to be accounted for by the smell-hypothesis, rest only on a rather loose kind of evidence, which can be adduced quite as abundantly in support of performances to which this explanation can be in no way applicable. In returning home do dogs "follow the identical route" by which they were taken away? There is no evidence even of the second-hand, loose, hearsay description, that this ever happened in a single instance.* The general impression, on the contrary, is that they despise the windings of rivers, turnpikes, and railways, and make for their destination by the most direct route. For example, and to add one more to the thousands of stories, we may mention that since we sat down to write we have received a letter from a gentleman telling us that about fifty years ago his paternal grandfather, living at Quorn, near Derby, sent two hounds by coach to his maternal grandfather living at Liverpool. Two or three days after their arrival they absconded together; inquiries were set on foot, and it is said they were seen swimming the Mersey at a point a little above Liverpool, where the river is of great width. They could be traced no farther, but after some time they made their appearance at Quorn, "foot-sore and in bad condition." Again, sheep, pigeons, and other animals that have not the miraculous scent of the dog, are believed on as good authority to find their way home through strange regions and from equally long distances.

Alluding to this class of alleged facts, Mr. Spalding, in the February number of *Macmillan's Magazine*, ventured to favour the view that through all the turnings and windings of a long journey the creatures somehow retain a perception of the direction of the place from which they were taken, and he further ventured to think that a hint of a similar faculty is to be found in some men. In this connection the facts with regard to savages would be most valuable. What Mr. Darwin calls the "trifling fact," communicated in his letter of last week, namely that his horse, which had been sent from Kent, *viâ* Yarmouth, to Freshwater Bay, in the Isle of Wight, on the first day that Mr. Darwin rode him eastward, was very unwilling to return towards his stable, that every time Mr. Darwin slackened the reins "he turned sharply round and began to trot to the eastward by a little north, which was nearly in the direction of his home in Kent;" this observation, together with the circumstance that with the fact before his eyes, Mr. Darwin's "impression was that he somehow knew the direction whence he had been brought," appears

* See letter of "J. T." p. 384. We have other letters to follow.

to us very important indeed. In the present state of our knowledge of the subject a few such "trifling facts" are worth more than many volumes of ingenious speculation.

We come now to the more weighty question which formed the subject of Mr. Darwin's first letter. Is it probable that instincts have any other origin than transmission by inheritance of acquisitions resulting from what we call individual experience? We are here at the very outside edge of human knowledge, in a region where no prudent person would venture to speak with confidence. Indeed the mode of origin recognised in the question still appears a "wild theory" to such respectable representatives of educated opinion as the *Spectator*. Had it been our good fortune to know as matter of certain history that the well-marked instinctive antipathy towards butchers of the dog King and his descendants was originally produced by ill-treatment, we should have had evidence of the most positive and direct kind, that sometimes at least instincts do originate in this way. There seems no hope of getting such evidence in this particular case; and indeed it may well be that the instinct in question is much more ancient than Mr. Darwin seems inclined to suppose. It is however to be hoped that before long some lover of animals will try his hand at actually producing a new instinct. But while Mr. Darwin regards it as probable that most instincts are examples of inherited experience, he thinks it "almost certain that many of the most wonderful instincts have been acquired independently of habit, through the preservation of useful variations of pre-existing instincts. Other instincts may have arisen suddenly in an individual, and then been transmitted to its offspring, independently both of selection and serviceable experience, though subsequently strengthened by habit. The tumbler-pigeon is a case in point, for no one would have thought of teaching a pigeon to turn head over heels in the air; and until some bird exhibited a tendency in this direction, there could have been no selection." The authority of Mr. Spencer may be adduced in support of Mr. Darwin's position. He speaks of "the natural selection of *incidental* variations," and of feelings that cannot be referred to "the inherited effects of experiences." Nevertheless, let us look closely at this matter. Will Mr. Darwin's view bear to be stated in such a way as to express more than the fact that in a great many instances we cannot conceive how the instincts originated? Will it bear to be put in this form: that it is almost certain that many of the most wonderful instincts had their origin in useful variations or sudden conjunctions of psychical states of such a character as could not by possibility have any relation to the experiences either of the individual itself or of its ancestry? Anything short of this will, it seems to us, scarcely amount to the contention that instincts have a mode of origin distinct from experience and heredity. That some other factor of unknown power may work along with experience and heredity in producing instincts, we are not in a position to deny. But still less are we in a position to say that there is such a factor, or what that factor is, or to admit that it ever operates independently of experience and heredity. We do not know how the tumbling of the tumbler pigeon began. But suppose we were certain that we had witnessed the very first performance of this kind, and saw that it arose suddenly and without any assignable cause: What then? How did the tumbling begin? To call it an incidental variation is but a way—and, because to some minds it looks like an explanation, a bad way—of stating our ignorance. But could we say so much as that it was in no way connected with experience and heredity? We think not. This tumbling is a fancy instinct, an outlet for the overflowing activity of a creature whose wants are all provided for without any exertion on its part. And if we had before us the evolutional history of the pigeon we might be able to point to some long obsolete instinct or useful action and say, behold, when on the wing, the superabundant energy of the creature has burst along the old long disused but not obliterated tracks, and see the strange result.

This is the direction in which we think it would not be unscientific to look for an explanation, should we ever have any such facts to explain. A similar line of remark might be followed with respect to what Mr. Darwin calls useful variations of pre-existing instincts. The question is, whence these variations? Further, just in proportion as these variations are slight, must it be difficult to say that they are not connected with experience—with the experience of the individual. In pursuing this inquiry we should doubtless come on the question, What is meant by experience? Everybody, it may be said, surely knows that. Perhaps. It is, we think, probable that the discovery might be made that we have not very clear and well-defined ideas as to the exact nature, extent, and limits of what we call individual experience. Of course we cannot now enter on such an inquiry.

SEPULCHRAL MONUMENTS OF CORNWALL*

II.

Nænia Cornubiæ. A descriptive essay, illustrative of the Sepulchres and Funereal Customs of the early Inhabitants of Cornwall. By W. Copeland Borlase, B.A., F.S.A. (London: Longmans; Truro: Netherton, 1872.)

MR. BORLASE, assisted by a party of friends, early in 1872, opened two barrows on the summit of one of the most commanding elevations in the district, about a quarter of a mile east of Trevelgue or Trevelga Cliff Castle, near St. Columb Minor. The most westerly is 250 ft. in circumference, 11 ft. high at the centre, and its greatest axis, having an east and west direction, is 100 ft. At a depth of 2 or 3 ft. from the surface, the entire substratum, to the amount of several hundred cart-loads, was burnt earth, as red and almost as fine as brickdust. Beneath it and towards the eastern side was a cairn of stones about 12 ft. in diameter, and 4 ft. high. Many of them had been brought from the neighbouring beach, and were blackened by fire. Under this lay a large spar stone, such as does not occur in the district, singularly flat for a stone of the kind, measuring 10·5 × 5·4 × 1·75 ft., on a level with the surrounding country, and covering a chamber 6·16 ft. long from N.W. to S.E, 2·5 ft. broad, and 2·75 ft. deep. Its sides were formed of four slate stones, 7 or 8 in. thick, and set on edge, on each of which the covering stone rested. The floor seemed to have been paved with slates, but they had been displaced, and portions of an unusually thick human skull were found below them.

The eastern or more conspicuous barrow was 80 ft. in diameter, 13 ft. high, and had a depression of 1·5 ft. at

* Continued from p. 337.

the summit. Immediately under the turf was a bed of stones, 3 ft. deep, and lying on a stratum of hard clay brought from a neighbouring valley. It contained a few human bones and ashes without any protection, and was 5 ft. deep. Under this was a second layer of stones, 3 ft. deep; and lower still an immense slate stone on a level with the natural soil, and covering a vault measuring 5·17 ft. long from N.W. to S.E., 2·8 ft. broad, and 2·25 ft. deep. The bottom was a pavement 6 in. deep, on which lay a human skeleton on its left side. The head was at the north-east corner nearly a foot from the end wall; the legs were bent at the knees, the arms stretched out so that the hands must have, at least, nearly touched the knees, and the body was contracted into a length of 4 feet.

Mr. Borlase holds that the Menhirs, or "Long Stones," of which there are many in various parts of the county, were sometimes tombstones merely, sometimes memorials of important events, and that they ranged from a romote antiquity far down into modern times.

In the hope of throwing some light on their origin the author recently examined the ground immediately around them. The Pridden Stone, close to the farm-house of Pridden, in the parish of Buryan, near Penzance, is an extremely rude mass of granite, 11·5 ft. above the ground, nearly 20 ft. in girth where broadest, and tapering towards the top. Below the natural level of the ground, a shallow pit, covered with a flat stone a foot in diameter, contained a few splinters of human bones, charred wood, and a layer of burnt brownish mould, the whole not sufficient to fill a quart pot.

On the farm of Tresvennech, in the parish of Paul, near Penzance, stands a granite menhir on the summit of elevated ground 11·5 ft. above the surface, and 4 ft. below. Though unhewn it is tolerably square at the angles, symmetrical, and perfectly upright. In 1840, a farmer, working near it, accidentally struck his tool against a horizontal flat stone 18 in. square, beneath which was a pit cut out of the clay soil, having its sides unprotected, and containing an urn 19·4 in. high, and 14·3 in. wide at the mouth. It stood mouth upwards, and contained the larger fragments of the calcined bones, and a molar tooth, of a human body; whilst the smaller pieces, together with wood ashes, were scattered throughout the pit. The urn was hand-made, and consisted of yellow clay found in the vicinity. Its interior was hard and black, but the exterior was not well baked. The handles were remarkably large and neatly put on, but differed in shape and size. A smaller urn, 5·5 in. high and 4 in. wide at the mouth, found 18 inches from the former, was also standing on its base, but without protection of any sort. It was filled with snuff-coloured powder.

The Sepulchral Mounds, or Barrows of Cornwall, whether of earth or stones, range from 15 to 100 ft. in diameter, and from 2 to 25 ft. in height. They resolve themselves into Cone, Bowl, Bell, Flat, and Ring barrows, but there is no instance of the Long, Druid, Egg, or Twin form, *i.e.* two surrounded by the same trench. The author recognises two pretty well-defined varieties of Ring-barrow:—1. Where the stones stand *on end*, at some distance from each other, and enclose only a piece of *level* ground. 2. Where the stones are set *on edge* (rarely *on end*) contiguous to each other, and enclose either a large rock, a few small mounds, or an area of uneven ground.

Of the first kind, there are four distinct examples within a circuit of eight miles in the Hundred of Penwith. Mr. Borlase is of opinion that all circles of *erect* stones owe their origin to the same design which attained its perfection in Stonehenge, and that the only question remaining is how far they can be regarded as sepulchral in their origin or use. He remarks that whatever may have been their *origin*, history and tradition seem to point rather to a civil than a religious *use* of them, and in confirmation quotes the "Iliad" (xviii. 503), a passage thus translated by Mr. Wright:—

> "Heralds the people checked. Elders meanwhile
> On polished stones in sacred circle sate."

The *Ring Barrows* of the second variety range from 10 to 100 ft. in diameter. The author has little doubt that they were originally sepulchral, and that they are cairns or barrows in an incomplete or demolished state.

At Trigganeris, in the parish of Sancreed, on the top of a hill, are two erect stones 17 ft. apart in a direction from N.N.W. to S.S.E., 7·3 ft. and 9 ft. high respectively. Nearly midway between them, but entirely on one side of a line joining their centres, a grave, 6 ft. long in an almost east and west direction, 3·25 broad, and about 5 ft. deep, was found cut with much precision in the natural clay. It contained nothing but the disturbed fine subsoil of the neighbourhood.

In 1818, a grave 8 ft. long, 3·5 broad, and 3 high, was found under a pile of stones 30 yards in diameter, near the "Cheesewring," in the parish of Linkinghorn, in East Cornwall. The bottom was one long flat stone; each side consisted of three stones, each end of one, and it had a cover of a single stone. Within it lay the remains of a human skeleton extended, having near the breast an earthen pot, containing, according to the workman who found it, a golden cup. The vessels were covered and protected with a flat stone 16 inches square, which leaned diagonally over them against the west wall of the grave. In this grave the following relics were also found, but subsequently lost:—a small piece of ornamental earthenware, a bronze spear head 10 in. long, a metallic rivet, as is supposed, and a few glass beads. The gold cup has been preserved, and is 3·75 in. high, 3·375 in. in diameter at the mouth, 2·5 ounces in weight, and its bullion value is 10*l*. It is perhaps worthy of remark that before the discovery of the cup there was a tradition in the neighbourhood of a "golden boat" having been dug up in a stone cairn near the Cheesewring.

It does not appear necessary to attach a nautical meaning to the word *boat*, for, unless we are in error, vessels for containing melted butter, sauce, &c., were formerly termed *boats* in Cornwall, as well as elsewhere.

Before quitting this cup it may be as well to add that we have elsewhere seen 1837 mentioned as the date of the discovery, instead of 1818, as given by Mr. Borlase.

Well-authenticated instances of inhumation are stated by the author to be extremely rare in Cornwall, and amongst these only two or three examples of the extended position actually occur, whilst only one of the contracted position can really be cited. He inclines to the opinion that the British copied the practice of cremation at a period not earlier than that of their con-

tact with the Romans; and thinks that a very doubtful answer must be given to the question, "Have there been found in Cornwall any interments which can with some certainty be said to have preceded the practice of cremation?"

Mr. Borlase entirely dissents from the opinion that articles interred with the deceased had reference to any view of utility in the next world, or, in other words, that they are the result of a matured belief in a future state; but guards himself from being supposed to assert that such a belief was non-existent in the days of the barrows.

The large *sepulchral urns* are of two kinds. 1. *Vase-shaped* vessels from 10 to 20 inches high, ribbed round the upper part, sometimes ornamented with small indentations, but never with the chevron pattern. 2. *Barrel-shaped* vessels from 8 to 13·5 inches high, invariably ornamented with the chevron pattern.

Vessels differing from the foregoing in size only, and ranging from 4·5 to 6 inches in height, are very frequently found in Cornish barrows, and sometimes in close proximity to the large ones.

Mr. Borlase has compiled, from county histories, papers read to various societies, manuscripts of older antiquaries—especially Dr. Borlase—and his own note-book, a detailed account of explorations and discoveries in the Cornish tumuli, made at different periods, from Norden's account in 1584, of "an auntient buriall at Withiell," to his own researches at Pradannack in November 1871. It may be doubted whether any part of his interesting volume exceeds this in value; and we indulge the hope that others—not antiquaries only—may follow his example, and collect and record the researches that have been made in the departments to which they specially devote themselves, in the counties in which they reside. We should greatly like to linger over this chapter, but both time and space forbid us to do more—and this we do most cordially—than congratulate the author on the successes which have attended his explorations.

He devotes his last chapter to "The Age of the Monuments," and thinks that his discoveries justify the conclusion that some, at least, of the most typical of the interments might be brought within historic times, and assigned to the early centuries of the Christian era.

The facts which seem chiefly to delight him are those he discovered in 1863, on Morvah Hill, and of which he gives, as "most worthy," the following "second notice":—

"Here was an instance of an interment in a cairn, where the body had been burnt on a central natural work surrounded by the usual ring of stones, the ashes placed in an urn of the usual chevron pattern, accompanied by the usual limpet and flint, protected by the usual Kist-Vaen, and finally covered in by the usual pile of stones. The whole arrangement, in short, being one of the most typical examples of the generality of barrows opened in the district. But here, in the very Kist itself, what should appear but late Roman coins of the third century! What is the most natural inference, then? That the coins must be thrown out of the question, because of the flint chip? or the whole structure referred at once to the Stone Age, thousands of years B.C., because it is encircled by large stones, or because the pottery is rude, and its ornamentation not curvilinear? Is it not rather the only fair course to admit at once that this interment, although possessing every characteristic of the so-called Stone Age, was placed here not earlier than the third century, A.D., that is, at the time when the coin was struck?" (pp. 263-4).

Being ignorant, perhaps, of some of the facts of the case, we do not presume to say that the author has not correctly interpreted his case, but as he seems resolved to ignore the question of secondary interments, which have undoubtedly taken place in many instances, and for aught that appears, may have occurred at Morvah, we hold *non proven* to be at present the only safe verdict.

We cannot take leave of Mr. Borlase's work without thanking him for the numerous well-executed illustrations with which it is enriched, and congratulating the publisher on the manner in which it has been got up.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

New Experiments on Abiogenesis

Having occupied myself for some time past with an experimental study of abiogenesis, I have followed with much interest the controversies on that question in recent numbers of Nature, and beg leave therefore to state to the readers of this journal the results of my experiments, which form in my opinion a not unimportant contribution to the solution of the interesting problem.

I fully agree with Prof. Burdon Sanderson in the confirmation of Dr. Bastian's statements regarding the well-known turnip-and-cheese experiments. A turnip decoction of the specific gravity 1·011—1·016, filtered and boiled with cheese (0·25—0·5 grm. to 50 c.c.), filtered again and neutralised, then boiled for 10 minutes and hermetically sealed, is after 2—3 days' exposure to a temperature of 30° C. swarming with *Bacterium termo*. It is however to be remarked that a too great concentration of the solution hinders the evolution of the Bacteria; the volume of the liquid employed should therefore not be too small, otherwise the boiling for 10 minutes will render the solution too much concentrated. Perhaps the negative results recorded by some experimenters are to be explained in this way.

Both turnip-decoction and cheese are a mish-mash of substances for a great part ill-defined and imperfectly known. It would be desirable to substitute for these materials some other mixture of better defined ingredients.

Instead of cheese can be used peptone (0·2 grm. to 50 c.c.) with the same result. The peptone is obtained by digestion of egg-albumen with artificial gastric juice, subsequently isolated and purified by repeated precipitation with alcohol.

In searching for a substitute for the turnip-decoction I found it available not to use the hermetically sealed vessels, but to experiment with free admittance of air. The recent explorations of Cohn, Burdon Sanderson, and Rindfleisch have shown that the germs of Bacteria are but sparingly present in common air, but notwithstanding it is a matter of course that in these experiments no other but perfectly filtered air can be admitted. After many trials the following mode of experiment was finally adopted.

I prepared a solution of the mineral salts, that are according to Cohn indispensable to the nutrition of Bacteria, viz. 1 grm. potassium nitrate, 1 grm. magnesium sulphate, 0·2 grm. calcium phosphate to 500 c.c. distilled water. (This mixture does not quite agree with the solution employed by Cohn. For various reasons, which will be stated elsewhere in a more extensive report of my experiments, I preferred this modification.) In 100 c.c. of this liquid were dissolved 2·5 grms. grape-sugar and 0·4 grm. peptone. About 50 c.c. of this solution was poured into a glass flask holding about 100 c.c. The mouth of this flask was beforehand polished flat, and a layer of hot molten asphalt laid on the flat brim. The liquid in the flask was then boiled for ten minutes over an ordinary Argand burner. The excessive frothing of the boiling liquid is easily prevented by using a small flame, and carefully regulating it when the froth is on the point of coming up, yet without allowing the liquid to

cease boiling. The ten minutes are reckoned from the moment the liquid begins to bubble freely.

The remarks of Dr. W. Roberts (NATURE, Feb. 20, p. 302) do therefore not apply to these experiments. Moreover, I observed frequently the temperature in the mouth of the flask, and found it always to be between 95° and 100° C. Therefore no part of the flask escaped the full effect of the germ-destroying heat.

While the boiling continued, a heated piece of unglazed flat earthenware tile was then pressed on the mouth of the flask; the solidified asphalt melted, and the piece of tile adhered, after cooling, firmly to the mouth of the flask. No air could then penetrate to the interior, except through the pores of the closing tile. The tile was 7 millimetres thick.

The previous heating of the tile is necessary, not only for melting the asphalt, but also for destroying the germs which possibly may adhere to the tile itself. This heating is effected in a Bunsen's burner, and raises the temperature of the tile to such an extent that a tuft of cotton-wool is scorched brown when pressed against it. The tile should not be too hot when it comes on the asphalt, lest the fumes arising from the decomposition of the asphalt should spread to the interior of the flask, and hinder the production of Bacteria.

The flasks prepared in this way were then exposed in a water bath to a temperature of 30—35° C. After two or three days the liquid was very turbid, very often a thick pellicle appeared on the surface, and flocky masses were swimming in the solution. The closing tile was then removed by melting the asphalt, and the microscopic examination showed myriads of *Bacterium termo* in lively motion, while the pellicle and the flocky masses consisted also of these organisms. *Micrococcus crepusculum* and *Vibrio serpens* were often present, but *B. termo* predominated. (The Bacteria were determined after Cohn's classification. "Beiträge zur Biologie der Pflanzen, II.")

The experiment conducted in this way yields always a positive result. Now three things are possible:—

1. The materials employed originally contained germs of Bacteria, which have simply developed themselves.
2. During the experiment germs have penetrated into the interior of the flasks.
3. The Bacteria have originated *de novo* in the liquid.

The first explanation is not admissible. For control-solutions treated exactly in the same manner, but composed in other proportions, remained under the same conditions perfectly free from Bacteria. These solutions were—

a. 100 c. c. of the above-named salt solution + 1 grm. ammonium-tartrate + 1 grm. grape-sugar.

b. 100 c. c. of the salt-solution + 1 grm. ammonium-tartrate + 0·2 grm. peptone.

Both these liquids are eminently suited to the nutrition and growth of Bacteria. That they nevertheless remained pure from these organisms proves that *none of the materials employed contained germs capable of resisting for ten minutes a temperature of* 100° C.

The second explanation is equally inadmissible. To prove this directly 1 grm. ammonium-tartrate was dissolved in 100 c.c. of the salt solution. This liquid was equally divided in two flasks, A and B. To A was added a trace of air-dust, collected in a little room where putrefying liquids were often standing, and then the flask was closed with a piece of tile in the above-described manner. B was boiled and closed as usual; but on the upper surface of the closing tile a considerable quantity of the same dust was loosely strewn. After twenty-four hours A becomes turbid, and swarms on the third day with Bacteria; B is on the eighth day still perfectly clear, and is then no longer examined. The conclusion is obvious: no germs of Bacteria do pass through the pores of the tile.

The only remaining explanation, is, in my opinion, this: under the above-described circumstances, Bacteria can arise without pre-existing germs. Not in any single case have I seen any other organisms than Bacteria—never fungi.

A certain concentration of the liquid is an important desideratum in these experiments. A specific gravity of about 1·012 is the most favourable. Greater dilution is a hindrance as well as greater concentration—at least when the above-named materials are employed. It is, however, not absolutely necessary to employ grape-sugar for raising the specific gravity up to 1·012. Common salt can do this just as well. Thus the following mixture is equally sufficient for generating Bacteria:—100 c.c. of the above-named salt solution, 2 grm. common salt, 0·2 grm. grape-sugar, 0·4 grm. peptone.

The first thing to be done now is to substitute for the grape-sugar and the peptone less complicated bodies. My experiments have been continued with this purpose.

This brief abstract may suffice for the moment. Shortly a more detailed communication and discussion will appear in one of the special journals.

D. HUIZINGA,
Professor of Physiology at the University of Groningen

Groningen, March 15

The Janssen-Lockyer Method

SINCE my letter which appeared in NATURE of February 20 there has been a letter from Dr. Huggins (also in NATURE, February 27, p. 320), and I see that Mr. Richard A. Proctor has likewise published a letter in the *English Mechanic* of March 7.

With respect to the former of these communications I have but one remark to make. I was ignorant that the domestic bereavement to which Dr. Huggins alludes occurred at the time when the eclipse reports from India reached this country. This circumstance undoubtedly explains why Dr. Huggins did not sooner make the observation alluded to; and had I known the coincidence in point of time between these two events I should not have made the remark to which he refers.

Mr. Proctor's letter certainly surprises me, especially as coming from one who holds a prominent official position in the chief astronomical society of this country.

1. In the first place I cannot understand what Mr. Proctor means when he says with allusion to the question proposed by Mr. Lockyer in his preliminary paper of 1866—"I have always judged from the form of the query that, as he now mentions, Dr. Stewart had suggested its wording." If Mr. Proctor will refer to my letter in NATURE of February 20 he will find it stated that I advised Mr. Lockyer to introduce his views in the shape of a question, which he accordingly did. The wording was Mr. Lockyer's own, being the result of his own cogitations on the subject, and all that I did was to suggest the putting of it in the form of a question.

2. Nor can I understand what Mr. Proctor means when he says—"I can admit very readily that Mr. Lockyer clearly recognised the principle of the method for spectroscopically studying the prominences when he asked the query. I do not indeed see how any person at all familiar with spectroscopic analysis could have failed to do so, after reading Dr. Huggins' account of his observations of T Coronæ."

When Mr. Lockyer suggested the application of the spectroscope to the sun's red flames he knew, no doubt, and made use of his knowledge, that in white solar light the spectrum is scattered, while in light from incandescent gases it is not; but his information on these points was not surely derived from Mr. Huggins. Was not Newton the first to show that a slit of white light is dispersed by refraction into a broad band or ribbon? I do not know whether Newton ever clearly enunciated that in consequence of this dispersion the ribbon was less luminous than the slit. Perhaps he thought that this was sufficiently understood, but at any rate he who after Newton first made this announcement cannot be said to have made a very startling discovery. I have the highest respect for the brilliant discoveries of Dr. Huggins, but I am quite sure that he does not claim as one of these the statement that "when the feeble light of a nebula is dispersed into a spectrum consisting of light of all refrangibilities, the spectrum is extremely faint."

In like manner the man of science who first showed that incandescent gases give out only a few spectral lines made a great discovery; while he who after this discovery first announced that such light will not be weakened by dispersion can hardly be said to have made a discovery at all.

Now these two discoveries of two different kinds of spectra have been most prolific. Swan has used them; Kirchhoff has used them in certain experiments of his in which the conditions were probably very similar to those in T Coronæ, and after Kirchhoff, Huggins, and after Huggins, Lockyer. Each of these and many more have applied those well-known principles in many ways, none of the observers claiming the principles, but each one claiming his own application, being at the same time perfectly willing to acknowledge his neighbour's just claims. For instance, Dr. Huggins says—"To Mr. Lockyer is due the first publication of the idea of the possibility of applying the spectroscope to observe the red flames in sunshine." Now this is precisely the state of the case, and I need not say anything more.

3. Then as to the advice to Mr. Lockyer to put his suggestion in the shape of a query, it ought to be remarked that it was a

preliminary paper, and that Mr. Lockyer intended to follow up and did follow up his suggestion with the requisite observations. But at that time neither Mr. Lockyer nor myself knew to what extent the spectroscope would throw light upon these red flames. What service I did was in stating my opinion that those red flames were probably gases, while the suggestion as to how to detect them was due to Mr. Lockyer. Had the red flames proved to be solid particles, the spectroscope would have afforded only meagre negative evidence of their existence.

Our ignorance on this point suggested to us the propriety of a query. It was only in this respect that the query was ambiguous, that is to say there was no doubt that the method suggested by Mr. Lockyer would throw a great deal of light upon the red flames if they proved to be gaseous, but the only doubt in our minds was whether or not they were gaseous.

4. I have tried as well as I can in justice to both of us, to remember and reproduce what took place in the conversation in 1866 between Mr. Lockyer and myself, and to show the reasons for the form in which Mr. Lockyer's suggestion was put. Probably Mr. Huggins announced it afterwards in a more complete form, and probably it has since been announced in a yet more clear and complete form, if this be possible. For we know that as a rule discoverers and inventors have no great power of expression, and if the prize is to be given for the clearest possible utterance of a truth, it will be very seldom won by the discoverer, but will very frequently be obtained by the popular writer. Nevertheless I fail to see that Mr. Lockyer's original query was at all ambiguous in the sense that Mr. Proctor suggests. How, I should like to know (adopting the words of the query), could the spectroscope afford us evidence of the existence of the "red flames at other times than those of a total eclipse, unless by dispersing the reflected light."

5. Mr. Proctor asks, To what end are we to inquire whether Mr. Lockyer would or would not have detected the lines without the information derived from the eclipse observations? As far as I can understand the question I quite agree with Mr. Proctor. I do not think the inquiry ought ever to have been made. When, however, it was suggested that Mr. Lockyer derived aid from the Indian observations it was surely allowable for him to deny the imputation.

6. I have sometimes thought that discussions too frequently arise from the attempt to compare together the labours of different men, when all that is necessary is a statement of facts and dates. It is a matter of fact that the Indian observers at a particular date and under particular circumstances, made certain observations and derived certain results. It is likewise a matter of fact that Mr. Lockyer, at a date slightly later and under certain other circumstances, made observations of another kind, from which he also derived certain results. Different minds are differently constituted; one will think more of the Indian observations, another of those of Mr. Lockyer. But why should the two be compared together, unless some good object is to be gained by the comparison?

7. Now I cannot see why Mr. Proctor in his letter should have made the comparison at all, but since he has done so, I must be allowed to object to his method of making it. "Surely," he says, "on this matter we must assign Mr. Lockyer only the credit arising from the fact that, possessing an instrument which made the work child's play, he saw the lines by the method described by Huggins nine months before in detail, and depending on a principle which Huggins had stated fully two years and nine months before." I have already endeavoured to dispose of the latter part of the statement, and indeed Mr. Huggins has disposed of it himself; but with regard to the first part of it, I conceive that the possession of an instrument which made the work child's play, forms one element of the credit due to Mr. Lockyer. At first his instrument was defective and unable to do what he wished, but his conviction that something was to be made out of the sun, if examined by a powerful spectroscope, was so strong, that after much delay on the part of the optician employed, and sundry other discouragements, he at last procured for himself an instrument with which he saw the red flames at the very first trial.

8. I should not have alluded to the concluding paragraphs of Mr. Proctor's letter were it not written by one who holds a high official position in the Royal Astronomical Society. To my mind it is most deplorable that the secretary of this society should conceive himself at liberty to make in a public journal unsupported statements reflecting discreditably upon a distinguished member of that society. It is bad enough when two private men of science abuse each other, but it is not to be tolerated when a high official of a society of standing descends into the arena. If he insists upon doing so it is surely not unreasonable to request that he will in the first place divest himself of his robes of office.

For my own part I have thought that Mr. Lockyer has attached only too much importance to the little help I gave him when we conversed together in 1866.

BALFOUR STEWART

Mr. Mallet's Theory of Volcanic Energy

WILL you allow me to make a few remarks upon Mr. David Forbes's critique, which has but just now met my eye, though published in NATURE of February 6 last, upon my translation of Prof. Palmieri's "Incendio Vesuviano," and more especially upon that gentleman's animadversions upon my views as to "the true nature and origin of volcanic heat and energy," a brief and incomplete account of which I have given in the "introductory sketch" prefaced by me to that translation.

Mr. Forbes commences (p. 260) with an important error as to a matter of fact, by referring to "Mr. Mallet's Dynamical Theory of Volcanic Energy," as published in the Proceedings of the Royal Society for 1872.

My paper as above was read in abstract only in June last to the Royal Society, and being reserved for probable publication in the Phil. Trans., nothing but the most meagre and incomplete abstract has appeared in the Proceedings of the Royal Society.

I have given a somewhat fuller, but still most incomplete, account of it in my "introductory sketch" above referred to. My paper, and the full statement of my views, with the proofs which give them validity, have thus as yet never been published at all, nor even verbally stated publicly, the paper being still—after eight months, I regret to say—in the hands of the referees.

When published—as the paper in some form will no doubt be—Mr. Forbes will find that his objections—so far as I can gather anything tangible from their statement in NATURE—have been anticipated, and I believe completely answered, in my paper, along with others, better founded, because based on fact, which, as it appears to me, Mr. Forbes's objections are not.

Mr. Forbes uses "theory" and "hypothesis" as though quite the same (p. 260). My hypothesis is simply undeniable, being no more than that our globe is a terr-aqueous planet subject to secular refrigeration; and upon that hypothesis I have built up my theory, that the evolution of volcanic heat is a necessary result, upon acknowledged physical laws of such refrigeration; and that from such heat so evolved—as the *primum mobile*—come in train all the other recognised volcanic phenomena: chemical, as in the fusion and combination of the constituents of rocks into definite and indefinite compounds, decomposition of many solid, liquid, and gaseous bodies; mechanical in the elevation and throwing out at volcanic vents of all or any of these: water, air, and the chemical elements known to exist in the crust of our earth being the only conditions needed, in addition to heat, to account for all that we know as to volcanic phenomena, as now active in our planet.

I claim to have been the first to apply "measure, number, and weight" to volcanic theory; and when men of science generally shall have had access to my statements, I trust it will be admitted that I have not shrunk from rigidly testing by calculation the adequacy of the source I assign for volcanic heat, nor of the mechanism through which its subsequent effects are produced, as seen in volcanic phenomena. I am at the disadvantage that I cannot expect to cumber your pages by reference to those proofs—they are the less necessary here, however—inasmuch as my reviewer, though affecting to discredit the adequacy of the origin I assign for the "quantity of heat requisite to melt up such vast volumes of rock matter as are known to proceed from volcanoes," does not present a single argument against it, and, in fact, appears unwillingly to admit it. He however proceeds to object generally to my views by the following statements. They are so vague and inconsecutive that, as far as possible, I shall endeavour to condense them in his own words:—"Admitting that the conversion of the mechanical *force into heat* is sufficient to effect the melting part of the operation, there remains the greater difficulty of explaining the chemical and mineralogical features which characterise volcanic phenomena. For although mechanical *force* is admitted to be convertible into its equivalent heat, which in turn may 'cause' chemical action, still no such forces, alone or in combination, can transmute one

chemical element into another, or give rise to products having at all times a definite chemical and mineralogical constitution, out of the incongruous materials likely to be met with" in the crust of our globe.

"Our knowledge of the mineral characters of that crust does not admit the supposition that the substance of the rocks occurring in so many different parts of the world could in all or in any but solitary instances when fused by mere heat afford products identical with those of known volcanoes.

"Volcanic products, no matter from what part of the world derived, are *identical in chemical or mineralogical constitution;* a result which indicates that they must be derived from some one common source, and not mere local accidents, as Mr. Mallet's *hypothesis* would require us to assume.

"For these and other reasons [none of which are suggested] it does not seem probable that this *hypothesis* will receive the adherence of either chemist, mineralogist, or geologist." The italics are mine.

Now I cannot help remarking that Mr. Forbes shows his very slender acquaintance with the vast subject he so jejunely disposes of, by the very language he employs; *force* cannot be converted into heat, equivalent or otherwise; *work*, *i.e.* pressure producing motion, is transformable into heat, and every other known form of energy. But passing this as well as the reiterated confusion between hypothesis and theory, I ask, is it a fact as stated, that volcanic products whencesoever derived, in time and in space over the whole globe, are *identical in chemical or mineralogical constitution.* I affirm unhesitatingly that it is not a fact, and I appeal for confirmation of my denial to every authoritative work on the subject, and to every well-informed mineralogical chemist.

Are the ancient basalts and trachytes identical with the modern ones, or with each other in different localities? Are the modern lavas of extinct or active volcanoes all over the world, or even at closely adjacent places, all identical? Are the highly liquid lavas of Otaheite, producing "Pele's hair," the same with the terrane lavas of Etna? Are the trachytes of Auvergne—the *Pierre de Volvic* so well known to French engineers, the same as those of Pozzuoli and of the Rhine? Are the products of the same volcanic basin ever identical—say the pumices and obsidians of Ponza, Ischia, and Lipari—with the innumerable varieties of lava of the same localities, and of the phlegræan fields and of Sicily? Are even the lavas of the same cone and during the same eruption always identical? Palmieri in the very report Mr. Forbes reviews, says (p. 105), "The *qualitative* analysis of the (Vesuvian) lavas always presents the same elements," with certain exceptions; "but with respect to *quantitative* analysis, two specimens of the same lava have their constituents in different proportion." Nay more, are even the crystallised minerals of definite chemical constitution, as segregated from the lava pastes or glasses, *identical* all over the world, or even for any one cone, or often for any one eruption? No, there is just that general similarity in the constitution of volcanic products that we should expect to result from the heating more or less, or the fusion together of the "incongruous" beds, siliceous, aluminous, magnesian, calcarious, mixed more or less with metallic oxides, or other compounds, and often with carbon, boron, and other elements all variously superposed or mixed, which constitute the known crust of our globe, along with most probably the materials of crystalline or other rocks below, the nature of which we can but guess at. There is just the same general similarity that is seen in the slags of all metallurgic furnaces, which fuse very similar materials to the volcano, but with a preponderance of some metal also. Are the slags of the same iron blast furnace *identical* even for any two tappings, though the working and charge is apparently the same? No, and for very obvious reasons. Are even the crystallised minerals that segregate from these slags, from the same furnace assumed, worked in the same way, always identical?

If Mr. Forbes will study Von Waltershausen's early and able work on Lavas, one scarcely known in this country, Zirkel's "Petrographie," Senft's "Kristallmischen Felsgemengtheile," and above all Blum's "Handbuch der Lithologie," amongst many others he will soon see how very baseless is the supposed fact on which he so confidently relies for his objection to my origin of volcanic heat.

But let us for a moment assume that it were a fact that all the volcanic products all over the world, and for all geologic periods, were "identical in chemical and mineralogical constitution," how would that form any relevant objections to the thermo-dynamic origination which I have assigned to volcanic *heat.* Or how would it help the old notion of a very thin crust and a universal molten ocean beneath, or the exploded one, that chemical action produces the heat, and the heat produces the chemical action.

Whatever be the origin assigned to the heat, it is within or below the heterogeneous solid crust of 10 to 40 miles thick, which we are acquainted with. More or less of that heterogeneous crust must be melted up, along with the material assumed everywhere the same of the molten ocean coming up through it from beneath.

It is proveable on merely hydrostatic grounds that the mass of such a molten ocean, if of materials such as are found in our earth's crust, could not be everywhere and in all latitudes identical in construction; but were it so, it must get contaminated and modified in passing through and melting the "incongruous" ducts of the crust bringing it to the surface.

On the other hand absolute identity everywhere in the volcanic products, did it exist, could prove nothing in favour of a universal ocean of ready-made lava as the source or origin of volcanic heat; but only that whatever might be the origin of that heat it was so circumstanced as to act on materials everywhere the same, and that these reached our surface without any action or mixture with the "incongruous" crust through which the molten matter came. There is just the same room for "local accident" in one case as in the other. A reviewer should at least be sure of his facts before he brings them into hostile array.

But again, what are the grounds for the assumption that according to my views, volcanic products of whatever sort are "the result of fusion by *mere* heat." I point out a true cosmical and thermo-dynamic origin for the heat itself, but under the actual conditions of volcanic foci and ducts, chemical actions must take place, as a consequence of the heat, and together vary the results of the reactions of all the materials present in fusibility, in aggregation, in their solid, liquid, or gaseous states, in their molecular conditions and in their chemical and crystallogenic combinations. This objection as little applies to anything I have written, as the irrelevant suggestion, that the transformation of energy "cannot transmute one chemical element into another."

I believe this disposes of whatever is tangible or worth remark in Mr. Forbes' strictures.

He ends, however, in a manner unusual I should think for an unbiassed reviewer, by uttering a sweeping prophecy, "for the reasons given [and above repeated], and others not brought forward, it is not probable that this hypothesis [*i.e.* my theory of volcanic energy] will receive the adherence of either chemist, mineralogist, or geologist." Prophecies, especially as to matters of science, are dangerous things, and the prophets would do well to rule by Swift's advice, as to utterances of another class, and never record one that can be falsified within a short time. It so happens that I am able already to explode Mr. Forbes's. Writing to me under date of Dec. 24 last (1872), Dr. Haughton, Professor of Geology of the University of Dublin, says—"I gave two lectures during the last term (Michaelmas) which were attended by many of the fellows, in which I developed your theory of volcanoes and gave you full credit. The whole system hangs well together and must make progress." Prof. Dana (in noticing this same book which Mr. Forbes so uncompromisingly condemns), as editor of the *American Journal of Science*, for the month of February, 1873, at p. 151, says: "His paper is the most important contribution to this department of geological dynamics that has ever been brought forward, and the work above-mentioned [*i.e.* Trans. of Palmieri] is by his share of it more than doubled in value." In a letter to me, Feb. 11, 1873, Prof. Dana says: "Your views throw great light on a hitherto mysterious department of geological science, and I have no doubt that they will speedily gain general acceptance."

I could add like expressions from some others. Now both Haughton and Dana are at once chemists, mineralogists, and geologists. They are both, also, sound physicists and mathematicians. So this prophecy is already falsified, and I am consoled with the notion that my theory of the nature and origin of volcanic energy may survive the unreserved condemnation to which Mr. Forbes has sentenced it, on the grounds that I have above examined, and without his ever having had access to the paper itself criticised by him. I might refute, too, some criticism on the book itself, which I cannot avoid calling unfair, and also not founded on fact. It is not true, for example, that the first forty-six pages of my introductory sketch "are but an abstract of my

previously published investigations into the theory of earthquakes" (p. 260). The reviewer may not have been able or not taken the trouble to distinguish the old from the new; but as a fact, the greater part of those forty-six pages is of matter never before published.

So also it is scarcely candid to object that "no reference is found to any of the Continental men of science who have done so much for terrestrial vulcanicity," which is contrary to the fact, for I have referred by name or by their labours to the few who have in any way advanced our knowledge as to the nature and origin of *volcanic heat*, without noticing that within that scope only was I by space obliged to confine myself, as stated in pp. 48, 49, 54, 76, &c.; the phenomena occurring at volcanic vents, which have chiefly engaged the attention of Continental and all other volcanic authors being avowedly outside my limits, and, I might add, but too often of secondary importance.

The nomenclature generally of my "Translation of Palmieri" is said to be objectionable, because such terms as sulphide of potass and terrochloride of ammonia are encountered. I have looked through the pages since without being able to discover these dreadful terms. However I am ready to take the reviewer's word that such a slip in proof correcting may be found in some place, and I humbly bow to such microscopic, profound, and valuable criticism, though, as stated, the conclusion is a good deal wider than its premises.

ROBERT MALLET

Enmore, The Grove, S.W., March 5

Effect of Resistance in modifying Spectra

IN a review of M. Guillemin's work "The Forces of Nature" which appeared in last week's *Athenæum*, the following reference, by M. Guillemin, to the experiments of M. Mitscherlich is quoted: "Suivant ce physicien il arrive que la presence de certaines substances dans une flame a pour effet d'empecher de se produire les spectres des autres substances, d'enteindre leurs raies principales." The English editor adds that the effect "may probably be explained by the observations of Frankland and Lockyer."

In relation to this subject of the extinction of the bands of one metal by another, you will perhaps permit me to quote a paragraph from one of the lectures which I have recently had the honour of delivering in the United States. The arcs of thallium and silver had just been compared, and their similarity of colour pointed out. The power of prismatic analysis to show that, notwithstanding the apparent identity of colour, the arcs really belonged to two different metals, was then demonstrated. The metals were afterwards subjected *together* to the action of the Voltaic current, and it was shown that the band of thallium fell midway between the two bands of silver. Hence the similarity of colour. The lecture then proceeds thus:—

"But you observe here another interesting fact. The thallium band is at first far brighter than the silver bands; indeed the latter have wonderfully degenerated since the bit of thallium was put in. The reason of this is worth knowing. It is the *resistance* offered to the passage of the electric current from carbon to carbon that calls forth the heating power of the current. If the resistance were materially lessened, the heat would be materially lessened; and if *all* resistance were abolished there would be no heat at all. Now thallium is a much more fusible and vaporisable metal than silver, and its presence facilitates the passage of the current to such a degree as to render it almost incompetent to vaporise the more retractory silver. But the thallium is gradually consumed; its vapour diminishes, the resistance consequently rises, until finally the silver bands are rendered as brilliant as at first."

In the spectra of mixed substances derived from the electric spark the action here referred to must come frequently into play. If neither the fact, nor its proposed explanation, be new, I would thank you to commit this document to your waste-paper basket.

JOHN TYNDALL

Royal Institution, March 1873

Perception in the Lower Animals

THE theory of taking olfactory notes by the way, as suggested by Mr. Wallace in explanation of the faculty possessed by animals of finding their way home, seems to meet with general acceptance amongst your correspondents; yet it totally fails to account for those instances in which the animal finds its way back by quite a different route to that by which it was taken away.

A good example is given by "F. R. G. S.," in the last number of NATURE; the anecdote of his riding-horse, by Mr. Darwin, also seems to illustrate this point. In an article on the "Consciousness of Dogs," in the *Quarterly Review*, of last October, the following remarkable instance, amongst others, is mentioned on indisputable authority. A hound "was sent by Charles Cobbe, Esq., from Newbridge, county Dublin, to Moynalty, county Meath, and thence, long afterwards, conveyed to Dublin. The hound broke loose in Dublin, and the same morning made his way back to his old kennel at Newbridge, thus completing the third side of a triangle by a road he had never travelled in his life."

Now as Mr. Wallace's theory does not explain these and similar instances, it clearly cannot be received as a solution of the question. Moreover, not only does the faculty exist in other animals not remarkable for their sense of smell, but we find it in cases where this sense has nothing to do with it. Take, for example, the direct homeward flight of the carrier pigeon. Under the same head may be brought the migrations of birds and fishes, and the habits of the turtle, as mentioned by Mr. Darwin.

The writer in the *Quarterly* suggests a sense of the magnetic currents of the earth—a sort of internal mariner's compass in fact. But it is difficult to see how this could have helped the dog to find its way from Dublin to Newbridge, for instance, unless it was also able to consult a map so as to ascertain the relative position of the two places.

It seems then that the problem still remains unsolved. Either we must extend almost indefinitely the range of smell and sight; or, we must suppose the existence of some peculiar sense of the nature of which we are ignorant, which enables its possessor to retain, as F. R. G. S. expresses it, "a constant perception of the bearing of its old home."

Bath, March 17

POSSESSION ISLES

AS the idea of occupying Possession Islands as a station for observing the Transit of Venus has been lately propounded, I have been requested to communicate to NATURE the results as to its climate, which we have obtained in this office from the logs of H.M.S. *Erebus* and *Terror*, which we are now re-discussing with a view to publication.

Possession Isles are in lat. 71° 56′ S., long. 171° 7′ E. H.M.S. *Erebus* and *Terror* were within lat. 70° to 72½° S., and long. 170° to 175° E. from 10th to 17th January, 1841. During these eight days the mean height of the barometer was 29·143, mean temperature of the air 29° 7, and of the sea 30°·5; the wind was variable, but chiefly from S. and SSW., force 6; the weather was clear ten times, cloudy twenty times, overcast eighteen times, from forty-eight double sets of four-hourly observations, while snow was noted nine times, and squally weather ten times.

The ships were within the same area on 20th and 21st February, 1841; and, during these two days, the mean height of the barometer was 28·920 inches, mean temperature of the air 23°·5, of the sea 30°·1; wind WSW. to SE., force 9 to 5; the weather was cloudy and overcast.

In addition I am permitted to enclose a letter from Dr. Hooker, which he kindly sent me in reply to my inquiries as to his reminiscences of his visit to these inhospitable regions, and which he has allowed me to publish.

Meteorological Office ROBERT H. SCOTT

Letter from Dr. Hooker

Possession Island, or rather Possession *rock*, is in a very inaccessible position. The chance of landing a well-equipped party upon it when reached, and the prospect of its subsequent removal by ships, if landed on, is very small. In any case I feel little uncertainty as to what would be the fate of a party left there for the winter, and the prospect of their seeing the transit would be absolutely *nil*.

To reach it we "took the pack" January 3, 1841, and had not penetrated it till the 9th, aided at last by a furious gale. We then discovered South Victoria, and traced its coast from lat. 70¾° to lat. 78°, without finding a spot where it was possible to approach the shore. During the

twenty-two days that we spent off that continent, we never effected a landing but twice, and then, with the greatest difficulty, on two small volcanic islets, without a particle of vegetation on them, of which one was Possession Island (Jan. 13), *a mere rock*. The ship was hove to two miles off; with the greatest risk a landing was effected, on a beach of large loose stones and stranded masses of ice. It was no sooner done than the recall flag was hoisted in the ships, which were reached just as a terrific fog came on, followed by a gale of wind; ten minutes more and all hands in the boats would have been lost, for the currents ran like sluices between the land, islets, and icebergs. So much for Possession Island. (Read Ross's account of the landing, i. 188, and especially the paragraph at p. 190.)

Take a glance at the meteorological registers in Ross's voyage for the month of January 1841, which was passed between S. lat. 66° 32′ and 78°. The mean temperature was 29°·02, max. 41°·5, min. 19°·5. It snowed on sixteen days; overcast, squally and misty was the usual weather, blue sky was rarely seen over more than a quarter of the heavens for a very few hours of the day, and for many days not seen at all.

In March between lat. 77° and 69½°, the mean temperature was 24°·28, max. 34°, min. 13°. Sky as in January.

In the following year our vessel went to the same seas. We "took the pack" December 17, and after being all but wrecked, penetrated it after fifty-six days of great peril, and proceeded to 78° S., never once seeing land.

During that January within 66° 32′, and 67° 21′ the mean temperature was 30°·46, max. 40°·5, min. 24°. It snowed on seventeen days, and we hardly ever saw blue sky.

In February between lat. 67° 18′ and 78° 12′, the mean temperature was 26°·68, max. 35°, min. 16°·5, and it snowed on twenty days. Blue sky was seen only on thirteen days. In 1842 the weather was worse than ever. In that year we tried to get south in the meridian a little east of Cape Horn, but never got beyond lat. 71½°, and then not till March 6th, having left the Falklands on the 18th December. In January of that year (1842) we were between lat. 63° 58′, and 64° 44′. The mean temperature was 30°·9, max. 45°, min. 23°·5. It snowed on sixteen days —sky as before.

February—between lat. 61° 37′ and 66° 01′. The mean temperature was 30° 50, max. 35°·5, min. 27°·5. It snowed on twenty-four days out of the twenty-eight! Blue sky was seen only on seven days, and this on six days over one-eighth of the sky, and on the 7th over one-fourth.

With such a midsummer climate I leave you to guess the position of a party in lat. 72°, cooped up through a winter on a rock a few yards long, covered with snow.

During the third year's cruise to the southward, Captain Crozier never once went to his cot, and we passed day and night with our hearts at the top of our throats.

The fact is, there is no summer or clear weather to be had, except by the rarest chance. For days and days we worked by Dead Reckoning alone. Storm, wind, and snow, are the prevalent summer phenomena. Still some seasons are not so bad as others, and Weddell got to 74½° in an open sea in the meridian where we barely reached 66°. (Signed) J. D. HOOKER

Royal Gardens, Kew, March 6

The following is the account of the landing alluded to by Dr. Hooker: —

"We found the shores of the mainland completely covered with ice projecting into the sea, and the heavy surf along its edge forbade any attempt to land upon it; a strong tide carried us rapidly along between this ice-bound coast and the islands amongst heavy masses of ice, so that our situation was, for some time most critical; for all the exertions our people could use were insufficient to stem the tide. But taking the advantage of a narrow opening that appeared in the ice, the boats were pushed through it, and we got into an eddy under the lee of the largest of the islands, and landed on a beach of large loose stones and stranded masses of ice. . . . . The island is composed entirely of igneous rocks, and only accessible on its western side. We saw not the smallest appearance of vegetation, but inconceivable myriads of penguins completely and densely covered the whole surface of the island, along the ledges of the precipices, and even to the summits of the hills, attacking us vigorously as we waded through their ranks, which, together with their loud coarse notes, and the insupportable stench from the deep bed of guano, which had been forming for ages, made us glad to get away again, after having loaded our boats with geological specimens and penguins. Owing to the heavy surf on the beach, we could not tell whether the water was ebbing or flowing; but there was a strong tide running to the south, between Possession Island and the mainland, and the *Terror* had some difficulty to avoid being carried by it against the land-ice. Future navigators should therefore be on their guard in approaching the coast at this place."

EARTHQUAKE WAVES

THE self-registering tide-gauges maintained by the United States Coast Survey at different points on the sea coast frequently exhibit, superimposed upon the tidal fluctuation, a succession of long waves, the origin of which is ascribed to distant earthquakes. In two notable instances, viz., the earthquake of Simoda in 1854, and that of Arica in 1868, the great ocean waves caused by the disturbance were distinctly registered in that way by the tide-gauges on the Pacific coast, and have been made use of for estimating the average depth along the lines of transmission. (See Coast Survey Reports for 1855, 1862, and 1869.)

Similar fluctuations were registered on the morning of November 17, 1872, shortly after local midnight, on the tide-gauge at North Haven, on the Fox Island, in Penobscot Bay, Maine. The fluctuations continued from midnight until nearly six o'clock in the morning, at somewhat irregular intervals of about seventeen minutes from crest to crest, with an average vertical range of nine inches, the greatest wave being at three o'clock, with a height of twenty inches.

No corresponding earthquake phenomena have come to the knowledge of the Coast Survey Office, and it is probable that if such was the case, the shock occurred somewhere under the Atlantic Ocean.

THE CHALLENGER EXPEDITION

H.M.S. *Challenger* cast off from the jetty at Portsmouth at 11.30 A.M. on December 21, with a low barometer. A strong south-westerly breeze was blowing, and the drum up; so that, especially in a season like the present, the prospect was not promising for the first few weeks of her voyage round the world.

The result justified the drum, and for a week we were knocking about the mouth of the Channel, and the Bay of Biscay, making slow progress southwards. It was perhaps as well to get a good shaking at first. It showed at once where there was a screw loose, and gave a chance to tighten it up. A sharp cyclone which caught the ship on her way from Sheerness to Portsmouth had already tested pretty fully the stowing of the apparatus, and although the *Challenger* rolls considerably when she is put to it (over 35°), not a single instrument shifted, and not a glass was broken, either in the zoological workroom, or in the chemical laboratory. Just before we got to Lisbon the weather improved a little, and we got some soundings and took one or two trial hauls with the dredge.

After leaving Lisbon on January 12 the wind was again fresh, but between Lisbon and Gibraltar we made some important experiments, and found, among other things, that we could work easily and successfully with the common trawl down to 600 fathoms. I am now writing about 100 miles north of Madeira, and since leaving Gibraltar the weather, though at first breezy, has been on

the whole fine. We have taken several successful navigative sounds at great depths, and we have trawled successfully at 2,125 fathoms, and recovered many interesting animal forms, several of them new to science, and others of extreme rarity and beauty. Still we must regard our work up to the present time as only tentative. The weather has been against us. It is altogether a new experiment to dredge from so large a ship, and it seems to present some special difficulties, or at all events to require some management. The weight of the ship is so great that there can be no "give and take" between it and the dredge, such as we have in the case of a smaller vessel. If there is any way on, the impulse to the dredge is irresistible, and seems to tend to jerk it off the ground. This difficulty can no doubt be met, but the only way of meeting it appears to be by using a length of rope greatly in excess of the depth—and having weights. A single dredging operation may thus occupy a great length of time, but in compensation we have the greater size and efficiency of this dredge. The few trials which we have already made have been all in the direction of improvement, and I have little doubt that under Captain Nares' skilful management what little difficulty is still felt will shortly disappear.

As I hope to contribute to NATURE from time to time a series of articles giving the results of our voyage, it may be well to commence by giving a sketch of the general scope of our operations, and the means and appliances at our disposal.

The *Challenger* is a spare-decked corvette of 2,000 tons displacement. This particular build gives her an immense advantage for her present purposes, as she has all the accommodation of a frigate, with the handiness and draught of water of a corvette. Sixteen of the eighteen 68-pounders which form the armament of the *Challenger* have been removed, and the main-deck is almost entirely set aside

LABORATORY OF THE "CHALLENGER"

for the scientific work. The after-cabin is divided into two by a bulk-head, and the two little rooms thus formed—still gay with mirrors, and pictures, and new chintz, and bright with home faces—are allotted to Captain Nares and myself. The fore cabin, a handsome room, 30 ft. long by about 12 ft. wide, into which these private cabins open, the captain and I use as a sitting room, the port-end with its writing-table and work-table, and its book-cases packed with old home favourites, being appropriated to my use and that of my secretary Mr. Wild; while the captain has arrangements at the starboard end of the same kind. Two sets of cabins have been specially built on the after-part of the main-deck for this difficult part of the scientific work. On the port side a commodious zoological work-room is occupied by the naturalist of the civilian staff, while the chart room corresponds with it on the opposite side. Towards the middle of the main-deck on the port side there is a dark room and a working room, for the photographer, and on the starboard side Mr. Buchanan has his chemical and physical laboratory.

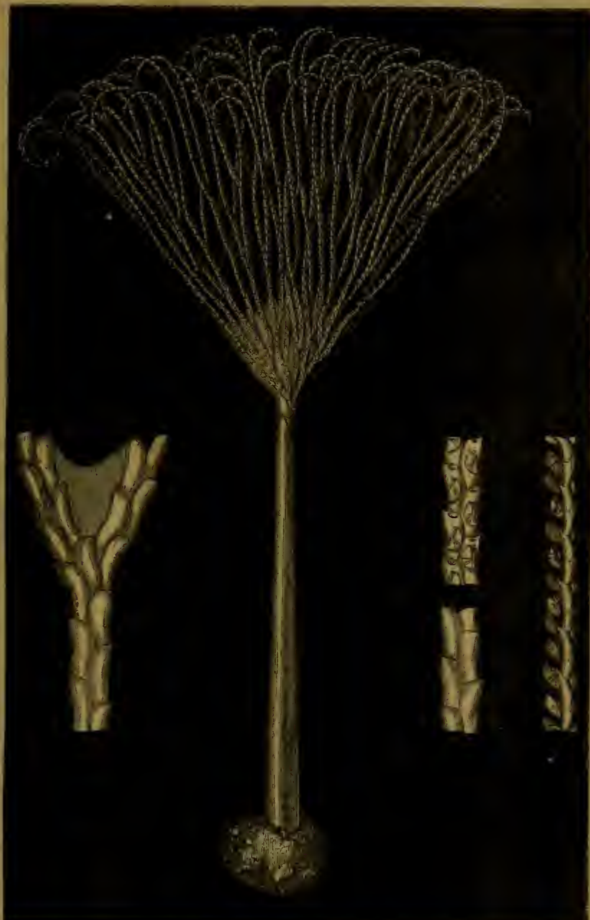
Nearly the whole of the fore-part of the main-deck is occupied by the dredging and sounding gear, Mr. Siemens's photometric and thermometric apparatus, and the more cumbrous of our machines, such as the hydraulic pump, the aquarium, and other very valuable articles, of which a detailed description will be given hereafter.

I feel justified in going even so far as to say that the arrangements for scientific work in the *Challenger* leave little or nothing to be wished for. Captain Nares and his officers not only do everything which care and skill can accomplish to further our objects, but, having naturally a certain advantage over the civilians in rough weather, they keep us up to the mark by the lively interest which they take in the success of our operations. There is a common mess in a large ward-room on the lower deck,

and the civilians have to heartily thank the naval men for the frank courtesy with which they have received them into their fellowship.

Dredging and sounding are carried on from the main-yard. A strong pennant is attached by a hook to the cap, and then by a tackle to the end of this yard. A compound arrangement of fifty-five of "Hodges' accumulators" is hung to the pennant, and beneath it a block through which the dredge rope passes. This arrangement appears to answer better than the old one of dredging from a derrick.

For the first two or three hauls in very deep water off the coast of Portugal, the dredge came up filled with the usual "Atlantic ooze," tenacious and uniform throughout, and the work of hours in sifting gave the very smallest possible result. We were extremely anxious to get some



NARESIA CYATHUS

idea of the general character of the fauna, and particularly of the distribution of the higher groups; and after various suggestions for modifications of the dredge it was proposed to try the ordinary trawl. We had a compact trawl with a 15 ft. beam on board, and we sent it down off Cape St. Vincent at a depth of 600 fathoms. The experiment looked hazardous, but to our great satisfaction this trawl came up all right, and contained, with many of the larger invertebrata, several fishes. Two of these belonged to the genus *Macrourus*, and another of large size was unknown to us, approaching in many respects the genus *Mugil*. All the fishes were in a peculiar condition from the expansion of the air contained in their bodies. On their relief from the extreme pressure, their eyes especially had a singular appearance, protruding like great globes from their heads.

After this first attempt we tried the trawl several times at depths of 1,090, 1,525, and finally 2,125 fathoms, and always with success.

Several fishes, most of them allied to *Macrourus*, were added to the list. Several decomposed crustaceans, and among the lower crustaceans at 1,090 fathoms, a gigantic amphipod, of the family Hyperina, allied to *Phronima*. The eyes of this creature are very remarkable, extending in two great facettio lobes over the whole of the anterior part of the cephalo thorax, like the eyes of *Aeglina* among Trilobites. This crustacean, which is three and a half inches in length, makes a splendid drawing, and reminds one of the old Eurypterids, is in process of description at the hands of Dr. von Willemoes Suhm.

Mollusca are very scarce in deep water, and our catches have hitherto been chiefly confined to such things as the species of *Nucula*, *Leaa*, *Verticordia*, &c., familiar through the deep dredgings of the *Porcupine*. Among the molluscoids a haul in 1,525 fathoms gave us a lovely thing, a bryozoan forming, out of branches closely resembling those of *Accromarchis neritina*, a graceful cup, the bases of the branches united by a transparent stem between two and three inches high, like the barrel of a quill, or the stem of a claret glass. This genus, which presents a general character totally different from anything hitherto known among recent Bryozoa, I mean to dedicate to Captain Nares, as an early recognition of the confidence and esteem which he has already fully gained from the scientific staff. *Naresia cyathus* certainly recalls, in a most singular way, the Cambrian *Dictyonema*, a form which I had, however, hitherto been inclined to refer to the Hydrozoa.

The Echinoderms have yielded some exceedingly interesting species to the trawl; among them several examples of the beautiful little urchins, of which one specimen was taken by Count Pourtales, in the Straits of Florida, and described by Alexander Agassiz under the name of *Salenia varispina*. It is undoubtedly a true *Salenia*, and to an advocate of the doctrine of the "continuity of the chalk," it is pleasant to see in the flesh this little beauty, which has hitherto been reckoned among the lost tribes.

Among the star-fishes two species of the genus *Hymenaster* have occurred, and the ophiurids are well represented chiefly by large examples of several species of the genus *Ophiomusium*.

All the hauls of the trawl, down to 2,125 fathoms, have yielded many specimens of a singular Holothurid, of which a description will shortly be published by Mr. Moseley. The animal is of a rich violet colour. Like *Psolus*, it has a distinct ambulating surface, with a central double line of water-feet. The body cavity is small, but the perisom is represented by an enormously thick layer of jelly, which rises on either side of the middle line of the back into a series of rounded lobes, each perforated for the passage of an ambulacral tube and corresponding therefore with an ambulacral foot. The upper pair of vessels of the trivium send out series of leaf-like sacs, richly loaded with pigment, which fringe on either side the ambulatory disc, and appear to be chiefly concerned in the function of respiration.

Sea-peas and Gorgoniæ have occurred frequently, always remarkable for their brilliant phosphorescence. Captain Maclear is giving special attention to this beautiful phenomenon. A *Mopsea*, which shone very brilliantly, gave a spectrum extending from the green well on into the red, while *Umbellularia* gave a very restricted spectrum sharply included between the lines *b* and D of this wonderfully rare sea-pea. We took with the trawl a very fine specimen, with a stem 3 ft. long, at a depth of 2,115 fathoms off Cape St. Vincent.

As usual in deep-sea work sponges preponderated, and the order has added several novelties, chiefly referable to the ventriculite group, the Hexactinellidæ.

Some fine new species of *Aphrocallistes* came up along the coast of Portugal, and off St. Vincent; with many spicules and more or less mutilated examples of Hyalonema, two or three species in fair condition of a species of *Euplectella*, with spicules which I cannot distinguish from those of *Euphalelles aspergillum*—the Venus flower-basket of the Philippines. The form of the two sponges is the same, but our own specimens are quite soft, the spicules not fused into a continuous siliceous network.

The physical and chemical observations will be fully detailed hereafter. The temperatures off the Coast of Portugal corresponded very closely with those taken in the *Porcupine* in 1870, and the *Shearwater* in 1871, below the first 100 fathoms through which at this season the temperature is nearly uniform. WYVILLE THOMSON

PROF. FLOWER'S HUNTERIAN LECTURES

LECTURES X. XI. XII.

THE fossil *Dasypodidæ*, or their existing allies, are found in America only. They may be divided into two classes, those closely resembling existing species, and those differing considerably from them. Most of the former have only been obtained in a fragmentary state; they have been studied by Lund; one was peculiar in having the teeth compressed from before backwards, instead of laterally. The latter class includes a well-known form, *Glyptodon*, of which there are several species, and perhaps more than one genus. An exhaustive monograph is in course of publication by Burmeister on the genus, and the material he has at his command at Buenos Ayres is very large. In 1839 Prof. Owen was among the first to describe it, he did so from the specimen now in the Museum of the College, giving it the name by which we know it. The Danish naturalist, Dr. Lund, at about the same time gave the name *Hoplophorus* to the remains of a very similar animal, and Burmeister considers that there is sufficient difference between the two type specimens of these authors, that of the latter having one less hind toe, to justify the generic name proposed by each being retained. In *Glyptodon* the carapace is proportionately thicker and stronger than in existing Armadillos; it is composed of distinct pieces in contact at their edges, but not anchylosed, except in aged individuals; it is never hinged transversely, so the animal could not roll itself up. A horny epidermis undoubtedly covered the shield, and hairs may have been present, as foramina are frequently found. The scutes vary in shape in different species, and are of different sizes in different parts of the same individual. The tail formed a thick cylindrical scute-covered column, which in some cases was armed with spines and swollen near the tips, like a giant's club. An approach to this peculiar shape is seen in the existing *Chlamydophorus*. All known species have eight molars above, and the same number below on each side of each jaw, in a long straight, nearly parallel series, running very far back. The teeth all grew from persistent pulps, and were therefore long and slightly arched, with two deep flutings on each side, whence the name. In structure they were much as in the Armadillos, and the presence of the grooves caused the central harder osteodentine to assume a somewhat gridiron shape, which was sometimes much elaborated. The front of the skull was much truncated, and a strong ossified septum was often present. Burmeister thinks that the animal possessed a trunk. The brain was proportionately very small, the olfactory lobes and cerebellum preponderating. Much of the skull was occupied by air cells and the molar roots. The descending zygomatic process was very large, to give origin to the masseter muscle; it is absent or nearly so in the Armadillos; it may differ in character from that of the Megatherium, probably arising from the maxillaries, as it was

perforated at its base by the infraorbital foramen. The vertebral column was most peculiar. Of the seven cervical vertebræ the first and sixth only were free, then came the "trivertebral bone" of Prof. Huxley, formed of the last cervical and first two dorsals; this was hinged ginglymoidly by the transverse processes on the next mass, which was composed of the rest of the dorsal vertebræ. The lumbar vertebræ were anchylosed together, but not to the last (the 13th) dorsal. The centra of the vertebræ were only represented by a thin bony plate which helped to form the tube for the spinal cord. Prof. Huxley thinks that the joint in the dorsal region was connected with the respiratory process, Burmeister considers that it enabled the animal to retract its head. The pelvis was much as in the Armadillo; the ilia were perpendicular. The symphysis pubis was slender, and is but infrequently preserved. The scapula possessed the characteristics of the class; the humerus had a supracondyloid foramen, and the radius and ulna were not anchylosed. The ungual phalanges were all hoof-like. As in the armadillos and seals, the 4th metarcarpal bone articulated with the cuneiform as well as with the unciform, and the 5th with the latter only; the pollex was absent. There was no third trochanter to the femur; the astragalus was normal; and there were four or five toes to the hind foot.

Of the other extinct Edentata there are none closely allied to the Ant-eaters, Ant-bears, or Pangolins. In the Upper Miocene of Darmstadt an ungual phalanx has been found, which like those of Manis is longitudinally split; it has been named *Macrotherium* by Lartet. Teeth have been found since, much like those of Dasypus, so it could not have been a Manis. At Pikerme similar remains have been found, which have been named as parts of *Ancylotherium*. These animals must form a separate division of the Edentata.

The *Ungulata* are the next great group to be considered. In their teeth they all tend to the typical formula $i. \frac{3}{3}\ c. \frac{1}{1}\ p. m. \frac{4}{4}\ m. \frac{3}{3} = 44$. The milk teeth are always functional and generally remain until the animal is nearly fully grown. The limbs are formed for simple support and progression, and there is no trace of clavicles. Except in the camels, the hoof encloses the ungual phalanx. Leaving Hyrax out of consideration it may be stated that the pollex and hallux are always absent. The class is found in all the world but the Australian region; they have not been found fossil in strata below the tertiaries, but in the oldest of them. They are absolutely divisible into two sub-classes from characters indicated by, but not entirely dependent on the structure of the feet. This division was indicated by Cuvier, but developed by Owen and H. N. Turner, Jun. Owen introduced the terms Perissodactylata and Artiodactylata by which these sub-classes are best known. In the *Perissodactylata* the middle toe is symmetrical, and there is typically one toe on each side of that, except in the Tapir and an early fossil Rhinoceros, *Acerotherium*. The astragalus has a single large anterior facet, entirely or mainly for articulation with the naviculare. There is a third trochanter to the femur, and there are never less than twenty dorso-lumbar vertebræ. The nasal bones expand posteriorly, and there is an osseous alisphenoid canal, as pointed out by Mr. Turner. In the *Artiodactylata* the axis of each of the feet is between the middle and fourth toe, and there is one toe outside each of these, but in the Peccary one is absent in the hind foot. The astragalus supports both the navicular and cuboid bones on nearly equal-sized facets. There is no third trochanter to the femur, and there are always nineteen dorso-lumbar vertebræ. There is no alisphenoid canal; the palate is completed by bone opposite the posterior molars. All these characters, especially when taken in connection with the teeth, make it easy, from a few fragments of the skeleton, to identify the sub-class to which fossil members of the class belong. In the Perissodactylata the persistent premolars and the molars are very much alike, being all double, but in the Artiodactylata the premolars are single, and therefore they do not form a uniform series with the molars; there is a third lobe to the last lower molar, except in an antelope, *Neotragus Saltiana*, as lately proved by Sir V. Brooke.

The earliest of the Perissodactylata are the *Lophiodontidæ*, from the lower Eocene. They are rather more generalised than the existing forms, as would be expected on the evolution hypothesis. The premolars are simpler than those behind. *Coryphodon*, the oldest, is known by its teeth, of which it possessed the typical forty-four, and a femur with a third trochanter. Its molars had two ridges with conical apices, whence Owen gave it its name, from a specimen dredged off Harwich. The feet are not known unfortunately.

Lophiodon itself is only known by its teeth and fragments of the skeleton; the upper part of the skull has not yet been found. It is a genus of the early and middle Eocene only. Its dental formula was $i. \frac{3}{3}\ c. \frac{1}{1}\ p.m. \frac{3}{3}\ m. \frac{3}{3}$. The molars are representatives of the type which runs through the whole class. In the upper jaw each tooth presented an outer wall, which developed into two well-formed cusps; running back from this were two transverse ridges, an anterior and a posterior, as they are termed. The anterior transverse ridge springs from in front of the anterior cusp, the posterior from in front of the one behind; these ridges, each by their curving backwards, enclose a space named the anterior and posterior sinuses. The posterior transverse ridge is absent in the premolars. The lower molars are simpler. The premolars were reduced in a manner which characterised the genus, the hinder part being cut away. Lophiodon is mainly found in the lacustrine deposits of the south of France; there were several species, varying in size from a full-grown Indian rhinoceros to that of a hare. Leidy, from the deposits of Nebraska, found a tooth exactly resembling those of this genus; he has named it *L. occidentalis*, but acknowledges the insufficiency of the evidence on which it is founded.

The next animals to be considered were about the size of the hare. *Pachynolophus* differed from Lophiodon in having seven pre-molars and molars in the upper jaw instead of six; the number in the lower jaw is not quite so certain, some having apparently six and others seven. The ridges of the teeth were less considerable and more broken into tubercles. In the London clay, near Herne Bay, a skull was found, named by Prof. Owen *Hyracotherium*. Mr. H. N. Turner was the first to point out that this animal was one of the Perissodactylata, and not as Prof. Owen at first supposed, allied to the Suidæ. The teeth very closely resembled those of Pachynolophus, each transverse ridge developing into a median smaller tubercle and a posterior larger one; the pre-molars were also considerably smaller than those behind. From the resemblance of the teeth it is evident that the French genus Pachynolophus and the English Hyracotherium must be considered to be one. *Pliolophus* is the name of a genus given by Owen to a specimen obtained from the London clay off Harwich, together with a humerus, femur, and three metatarsals. The forty-four teeth were present. There is no reason to suppose that this genus is different from Hyracotherium, the shape of the teeth and the size being identical; Prof. Owen himself states the possibility of their identity. The fact of there having been three metatarsals or metacarpals as they may be, found together, is a collateral one in favour of the animal having been Perissodactylate. From the above remarks it is evident that the names Pachynolophus and Pliolophus must be sunk in favour of Hyracotherium, as must also *Lophiotherium*, a name given by Gervais to an Upper Eocene specimen, known only by the mandible.

At the same time lived another small animal, *Miolophus*, known only from a fragment now at York. It differs from most ungulates in having only a single inner cusp to the molars, so causing it to resemble a typical pre-molar. Another form, *Microchœrus erinaceus*, is very aberrant, and its position is doubtful.

TESTIMONIAL TO DR. BENCE JONES

WE regret very much to hear that Dr. Bence Jones has been compelled on account of his health to resign the office of Secretary to the Royal Institution, a post which he has filled for so many years with equal honour to himself and advantage to the Institution.

His conviction of the value of original research, and of the special vocation of the Royal Institution to continue diligent in promoting it, was with him an unceasing stimulus to exertion. His attention to every detail left nothing neglected in the performance of his duties. His own scientific attainments have been of signal effect in maintaining respect for the Institution, and in procuring the co-operation of eminent men in the laboratories and lecture theatre. His love of the place and its memories has been shown by the pains he took to collect its early annals; including in this work an account of the discoveries of Young and Davy, and by his becoming the historian of Faraday.

The services of Dr. Bence Jones have been given under the pressure of important professional engagements, and latterly under the additional difficulties of failing health; and until now, when he has been reluctantly compelled to resign, he has never relaxed in the active prosecution of his honourable task.

We trust with the managers, however, that the aid of Dr. Bence Jones may not be altogether lost to the Institution; but that he will still afford to it the benefit of his counsels and experience. It is hoped that he may in future occupy a seat at the Board of Management; and further, that he will remain associated with the Institution by doing it the favour of accepting the position of Honorary Assistant-Secretary.

It has very naturally been proposed to present Dr. Bence Jones with a testimonial to be raised by subscription, and we feel confident that to so worthy a purpose there will be no lack of willing contributors. Individual subscriptions are limited to 3*l.* 3*s.* as a maximum.

It has been ascertained that the form of testimonial most agreeable to Dr. Bence Jones would be a bust of himself to be placed in the Royal Institution. Subscriptions to this testimonial may be paid either at the Royal Institution, or to "The Dr. Bence Jones Testimonial Account," at Messrs. Drummonds, the bankers, Charing Cross, who are authorised to receive the same.

CAPTAIN M. F. MAURY

MATTHEW FONTAINE MAURY, whose death, on Feb. 1, we recently recorded, was of French descent, and was born in Spottsylvania County, Virginia, Jan. 24, 1806. While still a child, his parents, who were in moderate circumstances, removed to Tennessee, where young Maury was sent to school. In 1825, when nineteen years old, he entered the service of the United States as midshipman, circumnavigating the globe in the *Vincennes*, during a cruise of four years. During this cruise Maury began his well-known "Treatise on Navigation," which was finished some years afterwards, and was for a long time used as a text-book in the U.S. navy. In 1836 he was made lieutenant and was gazetted astronomer to an exploring expedition.

In 1839, while travelling on professional duty, Lieut. Maury met with an accident which resulted in permanent lameness and unfitted him for active service afloat. What appeared then as a great misfortune to the lieutenant resulted indirectly in an increase of his fame, and in the performance of services of high value to science and humanity. The lame lieutenant was placed in charge of the Dépot of Charts and Instruments, out of which have grown the Naval Observatory and the Hydrographic Office of the United States. He laboured assiduously from the first day of his appointment to organise this dépot more efficiently than formerly. How completely he succeeded is well known.

While sailing around the globe in the *Vincennes*, Maury made many observations as to the winds and currents. These he continued in his subsequent cruises. When he became superintendent of the Hydrographic Office he determined to do something towards elucidating the intricate subject of ocean meteorology. The beginnings of this great undertaking were small. Maury obtained at first copies of such log-books as he or his friends could command. He noted the direction of the wind, the currents, &c., on the maps which he had prepared. As the information came in, districts were filled up and places pointed out for investigation. In 1842 the system had taken such consistency in his own mind that the lieutenant communicated to the U.S. Naval Bureau of Ordnance and Hydrography a plan for supplying model log-books to the commanders of vessels in the naval and merchant marine service. These log-books are so arranged that a systematic series of observations might be registered. The plan succeeded so well that in eight or nine years he had thus collected a sufficient number of logs to make 200 manuscript volumes averaging each about 2,500 days' observations each. These materials were digested by a board of officers appointed for that purpose, and the more immediate result of their labours was to show the necessity for combined action on the part of the maritime nations in regard to ocean meteorology.

In order that his labours might lead to some practical result, Maury wrought zealously to bring about a meeting of meteorologists belonging to all maritime nations; this led to the conference which met at Brussels in 1853, at which England, France, Russia, Portugal, Belgium, Holland, Denmark, Norway and Sweden were represented, and which produced the greatest benefit to navigation, as well as indirectly to meteorology. One of its most eminent and practical results was the establishment in London of the Meteorological Department of the Board of Trade. It recommended a model log-book for all vessels, in which a brief and uniform register of the principal meteorological phenomena are entered. The British Admiralty, the Royal Society, and the British Association entered heartily into Maury's plans, and aided him in every possible way; though we are ashamed to say that England is almost the only civilised country in the world that did not confer on this great benefactor of humanity some mark of honour: other countries loaded him with well-deserved tributes of admiration and gratitude for his services.

At the outbreak of the American civil war in 1861 Maury threw in his lot with the South, and did much to strengthen its maritime defences and enable it to hold out for so long as it did. He afterwards retired to England, where he lived for many years, and where he was presented with a handsome testimonial raised by subscription, he having lost nearly his all through his attachment to the unfortunate South. Having offered his services to the ill-fated Maximilian, of Mexico, the latter appointed him Imperial Commissioner of Emigration; and after the fall of that short-lived empire, Maury returned to the United States, taking up his residence in Virginia, where he lived until his death, on February 1 last. During his later years he devoted his time and efforts to urging his fellow-citizens of the south to leave politics alone and

apply themselves energetically to the development of the agricultural resources of their country.

In 1856 appeared the first edition of Maury's "Physical Geography of the Sea," which ran through many editions in the United States, was republished in England, and translated into several European languages. In this work he embodied the results of his researches on winds and currents, and propounded his well-known theory of the Gulf-Stream. Although it has been shown that this theory will not hold water, it does not in the least detract from the high and enduring value of the services he rendered to navigation and to meteorology. There is no doubt that to him is due the honour of having first shown how the latter could be raised to the dignity and the certainty of a science, though, forsooth, it is yet far enough from deserving to be called an exact one. But Maury was essentially a practical man in the best sense of the term; all his labours from beginning to end had for their one great aim, to render navigation more secure and more economical; and in the accomplishment of this aim he was eminently successful. The saving in time, in money, and in life to Britain alone which has resulted from Maury's labours it would be very difficult to calculate; through him have the characteristics of almost every mile of that part of the ocean over which the commerce of the world is carried, become as well known as any district which has been mapped by the Ordnance Survey. Dr. Neumayer, than whom no one is better entitled to pronounce judgment on such a subject, in his recent pamphlet on the Exploration of the South Polar Regions, in opposition to some ill-informed detractors of Maury's fame, speaks of him in the very highest terms; and though we hesitate to class him, as a recent writer has done, with Newton, he will certainly, and deservedly, occupy a niche in the temple of fame as a benefactor of humanity and a promoter of scientific knowledge, to which not many men ever attain.

NOTES

THE Duke of Devonshire, Chancellor of the University of Cambridge, has consented to preside at the meeting of the friends of the late Prof. Sedgwick, which is to be held in the Senate House at Cambridge, on Tuesday, March 25, at two o'clock, to consider what steps shall be taken to raise a memorial to the late professor. Many men of eminence are expected to attend. It is rumoured that the memorial is likely to take the appropriate form of a new geological museum at Cambridge.

WE are sorry to record the death of the interesting wasp referred to by Sir John Lubbock in his address at last year's meeting of the British Association. It slept away as it were on Feb. 20 last, first the head dying, then the thorax, and then the abdomen. It has been deposited in the British Museum.

IN order that local inspectors of weights and measures may more conveniently and accurately compare all commercial measures containing subdivisions of the imperial yard, with verified copies of the official standard measures of length, which have been legalised under the provisions of the Standards Act, 1866, by Her Majesty's Order in Council of March 24, 1871, a model of a new subdivided standard yard, attached to a simple, ingenious, and comparatively inexpensive comparing apparatus, has been constructed by Messrs. Troughton and Simms, under the direction of the Warden of the Standards. This comparing apparatus has been expressly designed as one that may be used by local inspectors of weights and measures for comparing ordinary commercial measures of length, and it may now be inspected at the Standards Department.

WE have received a short paper by Mr. Lewis M. Rutherfurd on the stability of the collodion film. Urged by the statements of Mr. Paschen, in the "Astronomische Nachrichten" in April last, Mr. Rutherfurd determined to subject the question between dry and wet process to a thorough examination, and made a number of measures, proving conclusively the superiority of the former to the latter. This conclusion is of great importance in connection with the approaching Transit of Venus. In all cases save two the distance was greater between the lines when the plate was dry than when wet, the mean excess of the nine measures is Rev. 0·0017, which is $\frac{1}{25,233}$ of an inch; it reaches in no case $\frac{1}{4800}$ of an inch. This result is no doubt due to the cooling of the glass plate, by the evaporation which takes place the moment the wet plate is taken from the plate-holder and exposed to the air under the micrometer. This excess of distance (Rev. 0·0017), would be caused by an increase of temperature for the dry glass of about 4° F. This consideration reveals a source of error in the use of wet plates which he had not before considered, since the same evaporation takes place no doubt during the long exposures given to star plates; the amount will vary according to the hygrometric state of the atmosphere, and may be met by reading wet and dry bulb thermometers. Mr. Rutherfurd's objection to the method used by Mr. Paschen, is that instead of being confined to an investigation of what happens to the collodion film between the moment of exposure wet and the moment of measurement when dry, it is a comparison of the actual state of the plate when dry with what it ought to have been had all the adjustments, manipulations, and instruments been perfect.

AN exhibition for proficiency in natural science will be offered for competition at King's College, Cambridge, on April 22 and following days. Its value is 80*l*. a year for three years. It is open to all British subjects under 20 years of age who bring a satisfactory certificate of good character. The examination will be in chemistry, physics, and physiology, with elementary papers in classics and mathematics. Applications should be sent to the tutor before Easter-day, April 13.

WE mentioned some months ago that Vice-Chancellor Bacon had decided against the validity of the late Mr. Yates's bequest to University College of endowments for the chairs of Geology and Mineralogy, and of Archæology, on the ground that the testator had never fulfilled his expressed intention of framing a code of rules and regulations for the manner in which the appointments to the professorships should be filled up. We are glad to see that the Lord Chancellor has, on appeal, reversed the decision of the Vice-Chancellor, so that the College will derive the benefits from the will designed by the testator.

A COMMITTEE has been formed among the members of the Berlin Geographical Society, and a plan has been drawn up in conjunction with the other geographical societies of Germany, for the completion from the west coast of Africa of the discoveries commenced by Dr. Livingstone from the East. The Committee propose that the expedition should start from the West Coast south of the Equator. The funds for the proper equipment and maintenance of the expedition are already partly provided.

THE Edinburgh Botanical Society has decided to offer triennially a prize of ten guineas, as an encouragement for practical research. The subject for competition is to be announced by the council at the commencement of each triennial period, and the successful competitor must have been a student who has attended the botanical class at the Royal Botanic Garden, Edinburgh, during at least one of the preceding three years, and who has gained honours at the class examinations.

THE mode in which the Fertilisation of Grasses, and especially of Cereals, is effected—a question of no small importance from an agricultural point of view—has recently been the subject of a series of observations by Delpino in Italy, and Hildebrand

in Germany; and the latter has published the result of his investigations in the "Monatsberichte" of the Berlin Academy. Both these acute observers are at issue with previous writers who maintained that the flowers of cereals, and especially of wheat, were self-fertilised in the unopened flowers, and consequently that the process could not be influenced by the wind. Hildebrand asserts, on the other hand, that impregnation takes place while the flower is open, and while the stigma is in a condition for the access of foreign pollen, that is, from other flowers. The opening of the flower of wheat, however, is completed in such a very short space of time that in a wheat-field there is probably never more than one in 400 of the flowers open at the same time. The contrivances by which in this case, as well as in other grasses, cross-fertilisation is at least rendered possible, are described in detail in the paper. In barley, on the other hand, the majority of the flowers never open, and self-fertilisation is the only condition possible. Delpino states, however, that there are in an ear of barley a very small number of flowers, differently constructed from the rest, in which cross-fertilisation is possible. In the oat the process is stated to vary according to the weather; in fine warm weather the flowers open freely, and cross-fertilisation is favoured; in cold wet weather they remain closed, and self-fertilisation is inevitable In rye, fertilisation from the pollen of other flowers is provided for. The agent in the dissemination of the pollen is scarcely ever insects, almost invariably the wind, to which end both stigma and pollen-grains are specially adapted.

We regret to say that last week we were led to state that Mr. Cleminshaw, recently elected to the Burdett Coutts Scholarship, received his scientific training in the Applied Science department of that College. We are requested to say that this is incorrect, as Mr. Cleminshaw was only a few months at King's College, where he did not study geology at all, while he was for several years at Rugby, to which school really belongs the credit of having trained so successful a student: moreover, Mr. Cleminshaw is, we believe, the third Burdett Coutts' scholar from Rugby within a few years. It is a pity that any school should require to make haste to claim possession of an honour which is not justly its due.

A living specimen of the extremely rare Liberian Hippopotamus (*Chœropsis liberiensis*), from Scarcies River, just north of Sierra Leone, arrived at Liverpool last week, but it unfortunately died on Friday, almost as soon as it reached its destination, Dublin. This second true hippopotamus was first described in 1844 by Dr. Morton, of Philadelphia, in the Journal of the Academy of Natural Sciences of that city. Prof. Leidy, in 1850, showed that its peculiarities rendered its differences from *Hippopotamus* more than specific, and in 1852 gave it the generic name by which it is now known. The full-sized animal is said to be no larger than a heifer, and the specimen under consideration, which was at least seven weeks old, weighed only 23lbs., whereas the one born in London last November weighed just upon 100lbs. shortly after birth. But the chief peculiarities of the genus *Chœropsis* are found in the teeth, as there are only two lower incisors instead of four, and the anterior premolars remain functional throughout the life of the animal, instead of being lost as is the case in *Hippopotamus*. In addition to these points in which *Chœropsis* is peculiar, it may be mentioned that the top of the head is convex instead of concave, the central upper incisors are slightly smaller than the outer, instead of larger, and the premaxillary bones are less developed than in Hippopotamus, from a young one of which, as M. A. Milne-Edwards remarks, it would be difficult to distinguish it externally.

From a memorandum affixed to the last part of Messrs. Sharpe and Dresser's "Birds of Europe," we learn that the latter gentleman has removed his entire collection of birds to No. 6, Tenterden Street, Hanover Square, where the work will in future be published, and which will henceforth be the head-quarters of the British Ornithologists' Union, as Messrs. Salvin and Godman have likewise removed their valuable collection of American birds to the same quarters, and Lord Lilford as well as Capt. Shelley have done the same with theirs.

A chrome mine has been discovered at Chanli, in the province of Larissa, Turkey in Europe. It is said to be rich.

On January 31, four shocks of earthquake were felt at Kara Hissar (query which) in Asia Minor. The shocks, of which the first two were rather violent, were repeated at intervals of twenty minutes. In the next afternoon, February 1, eleven more shocks were felt, which, though very sharp, only brought down three old abandoned houses. On Saturday, February 17, slight shocks of earthquake were felt in the island of Mitylene; the first at 1 a.m., and the second at 5.20 p.m. The oscillation was from west to east.—An earthquake that occurred on Dec. 29 last, at night, nearly destroyed the large town of San Vicente, in San Salvador, Central America. The upper half of the parish church fell, and many lives were lost.—At Bimlipatam, in India, a shock of earthquake was felt on January 25.—An earthquake is reported to have been felt at Peshawar, on Feb. 12. Its shock lasted for one minute.

According to the *Times of India*, a phenomenon occurred in several parts of the province of Kattywar, on Feb. 12, which gladdened the eyes of the English residents, and excited astonishment in the natives. On that day the ground was whitened by a hailstorm, a phenomenon unprecedented in the experience of the natives, hundreds of whom are reported to have set about gathering the hailstones as they fell, in order to turn them into "the best of confectionaries."

The collector of South Canara has brought to the notice of Government that the young shoots of the bamboo contain a bitter principle, which might be useful as a febrifuge.

The Council of the Society of Arts will proceed to consider the award of the Albert medal early in May next. This medal was instituted to reward "distinguished merit in promoting arts, manufactures, or commerce," and was awarded last year to Mr. Henry Bessemer. The members of the Society are invited to forward to the Secretary, on or before April 12, the names of such men of high distinction as they may think worthy of this honour.

The late Mr. George A. Clark, thread manufacturer, of Paisley, has left 20,000*l.* to Glasgow University for the establishment of four bursaries to be held by the successful competitors for four years, and to be so arranged that one bursary will be competed for each year. We hope the interests of science will not be forgotten in this matter.

The additions to the Zoological Society's Gardens during the last week comprise a Condor Vulture (*Sarcorhamphus gryphus*) from S. America, presented by Lieut. L. C. Strachey, R.N.; a Lapland Bunting (*Centrophanes lapponica*), presented by Mr. F. Bond; a Mantell's Apteryx (*Apteryx mantelli*); an Amherst Pheasant (*Thaumelia amherstiæ*) from China, and a Tamandua Ant-eater (*Tamandua tetradactyla*) from S. America, deposited; two Swainson's Lorikeets (*Trichoglossus novæ-hollandiæ*) from Australia; two Red-eared Bulbuls (*Pycnonotus jocosus*) from India; two Cardinal Grosbeaks (*Cardinalis virginianus*) from N. America; a Long-tailed Glossy Starling (*Lamprotornis æneus*) from W. Africa; a Pantherine Toad (*Bufo pantherinus*) from Tunis; some Natterjack Toads (*Bufo calamita*) from Africa; a Bearded Lizard (*Amphibolurus barbatus*) from Australia; five Banded Sea Horses (*Hippocampus ramulosus*) from France, and some Anemonies, all purchased.

THE BIRTH OF CHEMISTRY

VIII.

General Character of Alchemy and the Alchemists.—The Pretiosa Margarita Novella.—*An Alchemistical Allegory.—Alchemical Symbols.—Paracelsus.—Libavius.*

WHAT manner of men were the Alchemists? How did they preserve, cultivate, and transmit the wonderful delusions of their creed? We have endeavoured in a former article to show that the idea of transmutation arose from the old Greek idea of the conversion of one element into another; and the belief in the possibility of transmutation once admitted, the pursuit of the alchemist would naturally follow in a mystical and credulous age. As to the men themselves, their character was twofold; for there was your alchemist proper, your true enthusiast, your ardent, persevering worker, who believed heart and soul that gold could be made, and that by long search or close study of the works of his predecessors, he could find the Philosopher's stone; and there was your knavish alchemist, a man who had wits enough to perceive that the search was futile, and impudence enough to dupe more credulous people than himself, and wheedle their fortunes out of them on pretence of returning it tenfold in the shape of a recipe for converting lead into gold. These last we may dismiss at once. They abounded during the Middle Ages, and found easy dupes, whom they deceived by the most shallow tricks, as by placing a piece of gold in the crucible of transmutation together with volatile substances, and after many processes and much heating, they would show the little button of metal which had all along been present.

Of the true alchemist we have many pictures. The alchemist, the astrologer, the mystic, the wizard, were men of the same stamp. They often practised the same arts side by side. The same habit and attitude of thought belonged to one and to all, and became all equally well. Take the dreamy, maudlin, semi-maniacal Althotas, who has been described so well by Dumas:—"An old man, with grey eyes, a hooked nose, and trembling but busy hands. He was half-buried in a great chair, and turned with his right hand the leaves of a parchment manuscript." Note also his intense abstraction, his forgetfulness of the hour, the day, the year, the age, the country; his absolute and intense selfishness, and absorption, the concentration of the whole powers of his soul upon his one object. Or let us look at Victor Hugo's Archidiacre de St. Josas, in his search for the unseen, the unknown, and the altogether uncanny; the bitterness of his soul, his passionate musings, his conjurations and invocations in an unknown tongue; his own self, that wonderful mixture of theologian, scholar, mystic, perhaps not much unlike the divine S. Thomas Aquinas himself. Listen to his musings: "Yes, so Manon said, and Zoroaster taught:—the sun is born of fire, the moon of the sun; fire is the soul of the universe; its elementary particles are diffused and in constant flow throughout the world, by an infinite number of channels. At the points where these currents cross each other in the heavens they produce light, at their points of intersection they produce gold. Light!—gold! the same thing; fire in its concrete state. . . . . What! this light that bathes my hand is gold? The first the particles dilated according to a certain law, the second the same particles condensed according to another law! . . . For some time, said he, with a bitter smile, I have failed in all my experiments; one idea possesses me, and scorches my brain like a seal of fire. I have not so much as been able to discover the secret of Cassiodorus, whose lamp burned without wick or oil—a thing simple enough in itself." If we peep into Dom Claude's cell, we are introduced to a typical alchemist's laboratory—a gloomy, dimly-lighted place, full of strange vessels, and furnaces, and melting pots, spheres, and portions of skeletons hanging from the ceiling; the floor littered with stone bottles, pans, charcoal, aludels, and alembics, great parchment books covered with hieroglyphics; the bellows with its motto *Spira, Spera;* the hour-glass, the astrolabe, and over all cobwebs, and dust, and ashes. The walls covered with various aphorisms of the brotherhood; legends and memorials in many tongues; passages from the Smaragdine Table of Hermes Trismegistus; and looming out from all in great capitals, ΑΝΑΓΚΗ. Yet once again, look at Faust, as depicted by Rembrandt, or Teniers, unknown alchemist, if you wish for an alchemical interior.

But the hard-working and enthusiastic alchemist did not always follow the ideal of the novelist and artist; he often degenerated into a "dirty, soaking fellow," who lost what little learning he ever had by concentrating his mind on the one dominant topic, until it excluded every other idea and aspiration; then the pursuit became all absorbing, and the disciple of the art a mere drivelling monomaniac.

We will now look at one of the books which were cherished by the alchemists. Here is a little vellum-covered *Aldus*: date 1546. Paracelsus had been dead five years, and Cornelius

FIG. 14.—Allegorical representation of transmutation.

Agrippa, twelve years; Dr. Dee and Oswald Crollius were flourishing; Van Helmont and a host of known alchemists were unborn. Our little volume, full of quaint musings of a bygone age, has outlived them all, and yet it never drank of the *elixir vitæ*, although it pretended to teach others how to make it, and the philosopher's stone into the bargain. *Pretiosa Margarita Novella de Thesauro, ac pretiosissima Philosophorum Lapide* is the title; published with the sanction of Paul III. Pontifex Maximus, whose successor, be it remembered, established the *Index Expurgatorius*, and might possibly have prohibited the Precious Pearl of alchemy. The title-page goes on to tell us that it contains the methods of the "divine art," as given by Arnaldus de Villâ Novâ, Raymond Lulli, Albertus Magnus, Michael Scotus, and others, now first collected together by Janus Lacinius. The vellum cover is well thumbed, and in one place worn through, perhaps by contact with a hot iron on an alchemist's furnace-table, or by much use. There are no MS. notes, but on the title-page is the autograph of Sir C. Koby, or Hoby, and a favourite maxim, the first word of which alone—*Fato*—is legible. The date of the writing is perhaps 1580-90. Some initial letters of the text have been plainly illuminated in

FIG. 15.—Allegorical representation of transmutation.

red, by a loving hand; they were copied from a bible printed at Lyons in 1326.

As to the contents we have firstly an opening address by Janus Lacinius, then certain definitions of form, matter, element, colour, &c. Next, symbolic representations of the generation of the metals, and after this a woodcut representing the transmuta-

tion of the elements according to the dogmas of Aristotle.* After this we find the whole course of transmutation set forth pictorially and allegorically, as under. A king (see Fig. 14) crowned with a diadem, sits on high, holding a sceptre in his hand. His son, together with his five servants, beseech him on bended knees, to divide his kingdom between them. To this the king answers nothing. Whereupon the son at the instigation of the servants, kills the king and collects his blood. He then digs a pit into which he places the dead body, but at the same time falls in himself, and is prevented from getting out by some external agency. Then the bodies of both father and son putrefy in the pit. Afterwards their bones are removed, and divided into nine parts, and an angel is sent to collect them. The servants now pray that the king may be restored to them, and an angel vivifies the bones. Then the king rises from his tomb, having become all spirit, altogether heavenly and powerful to make his servants kings. Finally he gives them each a golden crown, and makes them kings (Fig. 15).

It is difficult to follow this from beginning to end, but there can be no doubt that the king signifies gold, his son, mercury, and his five servants the five remaining metals then known, viz. iron, copper, lead, tin, and silver. They pray to have the kingdom divided amongst them, that is to be converted into gold; the son kills the father, viz. the mercury forms an amalgam with gold. The other operations allude to various solutions, ignitions, and other chemical processes. The pit is a furnace; putrefaction means reaction or mutual alteration of parts. At last the philosopher's stone is found, the gold, after these varied changes becomes able to transmute the other metals into its own substance. At the end some rugged hexameters and pentameters warn the fraudulent, the avaricious, and the sacrilegious man that he is not to put his hands to the work, but to leave it for the wise and the righteous, and the man who is able rightly to know the causes of things.

After this allegory we have some remarks concerning the treasure and the Philosopher's Stone, and the secret of all secrets, and the gift of God. This is followed by a number of arguments against alchemy, and of course overwhelming arguments in favour of it. Among those who are quoted as alchemists are Plato, Pythagoras, Anaxagoras, Democritus, Aristotle, Morienus, Empedocles, and then, with a delightful disregard of age or country, we read, "Abohaby, Abinceni, Homerus, Ptolemæus, Virgilius, Ovidius." Then digressions on the difficulties of the art, the unity of the art, the art natural and divine; a slight history of the art, in which it is traced back to Adam, although Enoch and Hermes Trismegistus are mentioned as possible founders. A treatise to prove that this art is more certain than other sciences; on the errors of operation; on the principles of the metals; on sulphur; on the nature of gold and silver; and many general remarks on all alchemical subjects. These are the teachings which the *Pretiosa Margarita Novella* pours at the feet of the wise among mankind, by the aid of Paulus Manutius, bearing his father's name of Aldus, and by the grace of the Venetian Senate.

Many attempts were made by the alchemists to explain the origin of the metals; some regarded them as natural compounds of sulphur and mercury, others affirmed that the action of the sun acting upon and within the earth produced them, and that gold was in truth condensed sunbeams; many believed that metals grew like vegetables, indeed it was customary to close mines from time to time to allow them to grow again. Basil Valentine, as we have seen, regarded them as condensations of a "mere vapour into a certain water," by which latter we suspect he meant mercury. Perhaps the most absurd account of the origin of certain things is given by Paracelsus in his treatise, "De Natura Rerum," in the following words, which will show also how utterly nonsensical and unintelligible alchemical language could be, and for that matter very generally was. "The life of metals," he writes, "is a secret fatness; . . . of salts, the spirit of aquafortis; . . . of pearls, their splendour; . . . of marcasites and antimony, a tinging metalline spirit; . . . of arsenics, a mineral and coagulated poison . . . The life of all men is nothing else but an astral balsam, a balsamic impression, and a celestial invisible fire, an included air and a tinging spirit of salt. I cannot name it more plainly, although it is set out by many names."

The peculiarly secret and mystical language which the alchemists adopted was intended to prevent the vulgar from acquiring the results of their long-continued labours. Their language purported to be intelligible to the true adept; but as a rule the alchemists of one age gave various interpretations to one and the same secret communicated by their predecessors. Long recipes for the preparation of the Philosopher's Stone exist, which the authors have generously (as they tell us) given

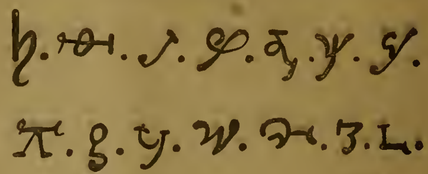


Fig. 16.—Symbols of Lead from Italian MS. of the seventeenth cent

to the world, after much labour, for the benefit of their fellow men. The obscurity of the science was increased by the multiplication of symbols; the presence of which in alchemy clearly points to its connection with astrology and the sister sciences. In time alchemical symbols multiplied almost as much as astrological symbols. In an Italian MS. of the early part of the seventeenth century which we have before us, mercury is represented by 22 distinct symbols, and 33 names, many of which are of distinctly Arabic origin:—such as Chaibach, Azach, Jhumech, Caiban. Lead is represented by the symbols in Fig. 16, and in addition to its ordinary alchemical names, is called Okamar, Syrates, Malochim, and others. The designation of substances as "the green lion," "the flying eagle," "the serpent," "the black crow," and so on, also led to considerable confusion. Both names and symbols were used in a somewhat arbitrary fashion.

It is somewhat strange to think that alchemy should have once received the serious attention of the legislature in this country. In 1404 the making of gold and silver was forbidden by Act of Parliament. It was imagined that an alchemist might succeed in his pursuit, and would then become too powerful for the State. Fifty years later Henry VI granted several patents to people who thought they had discovered the philosopher's stone; and

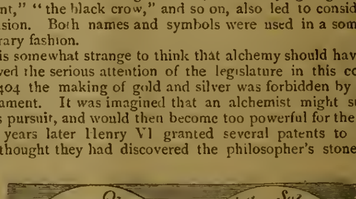

Fig. 17.—Designs from Mangetus (*Bibliotheca Chemica Curiosa*)

ultimately a commission of ten learned men was appointed by the King to determine if the transmutation of metals into gold were a possibility. We must now leave the subject of alchemy. Those who desire to study it more deeply will find a great mass of matter in the *Bibliotheca Chemica Curiosa* of Mangetus;

* See the first of these Articles.

but if they will take our advice, they will not waste much time in studying the history and progress of a futile and false art.

With Paracelsus (b. 1493, d. 1541), a somewhat new phase of the science of chemistry appeared. By pointing out the value of chemistry as an adjunct to medicine, he caused a number of persons to turn their attention to the subject, and to endeavour to ascertain the properties of various compounds. Thus he helped to withdraw men from the pursuit of alchemy, by asserting that the knowledge of the composition of bodies, which had necessarily been forwarded by alchemy, was of importance to the human race, for the better prevention and curing of their ills. In the way of discovery or research, Paracelsus did little. He mentions zinc and bismuth, and associates them with metallic bodies, and he makes considerable use of several compounds of mercury, and of sal ammoniac. Paracelsus compares the alchemist of his day with the physician, and speaks of the former in the following terms:—"For they are not given to idleness, nor go in a proud habit, or plush and velvet garments, often showing their rings upon their fingers, or wearing swords with silver hilts by their sides, or fine and gay gloves upon their hands, but diligently follow their labours, sweating whole days and nights by their furnaces. They do not spend their time abroad for recreation, but take delight in their laboratory. They wear leather garments with a pouch, and an apron wherewith they wipe their hands. They put their fingers amongst coals, into clay, and filth, not into gold rings. They are sooty and black like smiths and colliers, and do not pride themselves upon clean and beautiful faces."

Among the Paracelsians we find Oswald Crollius, who mentions chloride of silver under the long-retained name of *luna cornea*, or horn-silver, from its peculiar horny appearance and texture after fusion. He was also acquainted with fulminating gold.

The name of Andrew Libavius (died 1616) deserves mention, because he sought to free chemistry from the mazes of alchemy and mysticism in which it was involved. In this he to some extent succeeded; and he appears also to have been a patient worker in the field of the science which he did so much to promote. He discovered the perchloride of tin which is even now called *fuming liquor of Libavius*; he also proved that the acid (sulphuric acid) procured by distilling alum and sulphate of iron, is the same as that prepared by burning sulphur with saltpetre. Libavius was great at the making of artificial gems, and was able to imitate almost any precious stone by colouring glass with various metallic oxides. G. F. RODWELL

SCIENTIFIC SERIALS

THE *Zoologist* continues Dr. J. E. Gray's catalogue of the whales and dolphins inhabiting or incidentally visiting the seas surrounding the British Isles.—The Rev. A. C. Smith gives the results of the observations of Dr. Rey, of Halle, on the colouring of cuckoos' eggs, which are in favour of Dr. Baldamus theory.—From notes by Mr. J. Sclater and Mr. J. Gatcombe, from Castle Eden and Plymouth, we find that the glaucous gull has been obtained in both places, and the winds have driven ashore several other sea-birds, petrels, &c.

THE *Monthly Microscopical Journal* commences with the excellent address of the president of the Microscopical Society, the perusal of which, from the enthusiasm exhibited, will convince sceptics that there is a fund of enjoyment in science equal to that in other mental occupations.—Mr. Parker also contributes a paper on the development of the skull in the thrushes.—The Rev. S. L. Brackey has a paper on reduced apertures in immersion objectives, a subject on which Mr. R. B. Tolles and Mr. F. H. Wenham have a correspondence.—There is a short and severe review of Dr. Bastian's "Beginnings of Life."—Mr. S. Wells has a paper on the structure of *Eupodiscus Argus*, and G. W. Royston-Pigott one on spurious appearances in microscopic research.—Captain T. H. Lang gives a short abstract of Prof. Smith's "Conspectus of the Diatomaceæ," which has appeared in the *Lens*.

PETERMANN'S *Mittheilungen* (19 Band, 1873, ii). The first paper is another contribution to the literature of North Polar Exploration by J. Spörer, in which he shows the importance to science and humanity of records of exploration. One of the maps in this number shows the route followed by two Russians, Pawlinow and Matusowski, in their politico-commercial expedition of 1870, in Western Mongolia. Herr Fricke, a German merchant who has extensive connections both in East and West Africa, writes, giving several interesting details concerning the state of trade with the interior of South Africa, both from the east and west coast, showing that European connections with the interior extend much further than is indicated in our geographies and maps.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 13.—"Note on Supersaturated Saline Solutions." By Charles Tomlinson, F.R.S.

"Visible Direction: being an Elementary Contribution to the Study of Monocular and Binocular Vision." By James Jago, M.D. Oxon., A.B. Cantab., F.R.S.

Anthropological Society, March 11.—At this, the first meeting of this Society, the rules proposed by the Organising Committee were adopted, subject to confirmation at the first Annual General Meeting; and the following officers were elected:—President—Dr. R. S. Charnock, F.S.A. Vice-Presidents—Capt. R. F. Burton, F.R.G.S., and C. Staniland Wake. Treasurer—Joseph Kaines. Council—Dr. J. Beddoe, H. B. Churchill, Dr. Barnard Davis, F.R.S., John Fraser, Dr. G. Harcourt, Dr. Sinclair Holden, Dr. T. Inman, Dr. Kelburne King, Dr. J. Barr Mitchell, and T. Walton. Hon. Sec.—A. L. Lewis. Hon. For. Sec.—Dr. Carter Blake. This Society has been founded in consequence of a difference of opinion among the members of the Anthropological Institute, and a letter from Capt. Burton, the well-known traveller, heartily supporting the new organisation, was read.

Geologists' Association, March 7.—Henry Woodward, F.G.S., &c., president, in the chair.—"On the Geology of Brighton," by Mr. James Howell. Surface indications did not, he believed, afford evidence that the northern portion of the Downs had been submerged since its upheaval. Historical documents, submerged forests, and the shallowness of the sea's bottom, afforded abundant proof of the great encroachment of the sea along this part of the coast of Sussex during the historic period. The site of Old Brighton was stated to be seaward between East and West Streets, and not, as Lyell states, where the chain-pier now stands; and the coast line at the period when the Brighton Valley was an estuary of the sea and a river, was very different from what it is now. The geological formations at Brighton were stated to be six, viz. silt in the valley, brick-earth of Hove, the Elephant-bed, Templefield deposit, plastic clay of Furze Hill, and the upper chalk. The present paper embraced Mr. Howell's observations of the first three. In the lower portion of the silt and the coombe rock beneath it, are embedded immense numbers of water-rolled sandstones, similar to the sarsenstones distributed over the surface of the downs; but whether of Wealden or Tertiary origin is unknown. The brick-earth is a later formation than the elephant-bed upon which it everywhere rests, though the fossiliferous remains embedded in it are the same, viz., those of the mammoth, horse, red-deer, whale, and shells of an Arctic type. If, as Mr. Godwin Austen tells us, brick-earth is the wash of a terrestrial surface, how are we to account for the marine remains embedded in it? The pebbles of Palæozoic rocks, found in the old sea-beach under the elephant-bed, were stated to have come from France, when that country was united to Britain, having travelled along a beach once extending from Brighton to Calvados. The observations of Mr. Howell, of how pebbles and pieces of rock travel along a coast, aided by sea-weed to which they may be attached, supported this opinion. The author in conclusion opposed the opinion entertained by the geological section of the British Association during their visit to the Kemp Town section of the elephant-bed, that this remarkable deposit was formed by ice-action, and adduced the fact that the materials composing it are all water-rolled as corroborating the opinions of Webster, Mantell, and Lyell.

DUBLIN

Royal Geological Society, Jan. 8.—Professor Macalister, president, in the chair.—The Rev. Dr. Haughton, F.R.S., read a paper on Stirm's Fertiliser, from New Hampden, U.S.—Rev. Maxwell Close read some Notes on the High Level Gravels near Dublin.

Feb. 12.—This was the annual meeting. The outgoing president, Professor Macalister, delivered the annual address,

selecting for the theme of his discourse, the subject of Micro-petrography—a subject in which a vast amount of work remains to be done—one, it is feared, not so much known as it deserves to be, and much misunderstood. Workers are needed to follow up the lines of research of Rosenbusch, Lasault, and Fuchs, who are working out the correlation of petrography and petrology, the structure in regard to the position of the rock mass. As an an appendix to his address, Prof. Macalister gives an important bibliography of the subject of Microgeology. Prof. E. Hull, F.R.S., was elected President for the ensuing session.

PARIS

Academy of Sciences, March 10.—M. de Quatrefages, president, in the chair.—M. Berthelot took his seat as a member of the Academy. The following papers were read:—On Father Secchi's new hypothesis by M. Faye. The author replied to the Rev. Father's late note by proving that he had first stated that the solar spots were craters of eruption, and next that they were not eruptions, but were caused by them being in fact the erupted matter cooled by its passage above the chromosphere, the faculæ being the centres of eruption.—M. Faye showed this to be incompatible with the observed facts, the spots being surrounded with faculæ, whereas, according to Secchi's last theory, they ought to surround faculæ.—On the circulation of solar hydrogen, with an answer to some remarks by M. Tacchini, by M. Faye, treated of the spot phenomena; the author thinks that hydrogen is drawn down by the cyclones and returns to the surface around them. He also suggested that D_3 would probably be found to belong to a very rarified hydrocarbon of the acetylene series.—On the density of the vapour of phosphoric chloride, by M. Wurtz, who found that when precautions were taken, to prevent dissociation, the normal two volumes was occupied, experiment giving 7·226, and theory requiring 7·217.—On the springs of the Seine basin by M. Belgrand.—Researches on the action of the tympanic chord on the circulation in the tongue, by M. A. Vulpian.—On the industrial production of cold by the detention of permanent gases and of air in particular, by M. Armengaud.—On the production of silent electric discharges and on their mode of action, by M. Boillot.—Experiments on putrefaction, &c., by M. Laujorrois.—On the assimilability of phosphates, by M. H. Joulie.—A note on the unity of force and of matter, by Madame C. Royer.—On the theory of solar spots, by M. Tacchini, was an answer to M. Faye. The author contends that the hydrogen carried down by the cyclones ought to return up their axes, and not around them; and as this is not the case, he thinks that his criticisms remain unrebutted.—A paper on the trajectories of points, &c., by M. Mannheim.—On benzylated naphthalin, by M. Ch. Frotté. The body in question is produced by the action of benzylic chloride on naphthalin in the presence of powdered zinc.—On a combination of urea with acetylic chloride, by M. D. Tommasi. An atom of hydrogen in urea is replaced by the acetyl compound.—On the composition of guanos, &c., by M. A. Baudrimont.—On asphyxia and on the causes of the respiratory movements in fishes, by MM. Gréhant and Picard.—On the influence of ammonia in manufactories where mercury is employed, by M. J. Meyer. The author asserts that he has succeeded in stopping all the terrible effects of mercurial poisoning in the silvering rooms of the Saint Gobain glass works by watering the floors every evening with half a litre of commercial ammonia. He states that since 1868 he has not had a single workman attacked.—On the saccharine matter of mushrooms, by M. A. Müntz.—On the normal microzymes of milk as the cause of the coagulation and alcoholic, acetic, and lactic fermentations of that liquid, by M. A. Béchamp.—On the quaternary fossils collected by M. Œlert at Louverné (Mayenne), by M. A. Gaudry.—On the existence of man in Alsace during the glacial epoch, by M. Ch. Grad.—On the movements of the atmosphere as regards the prediction of weather, by M. de Tastes.—On the use of vermouth, by M. E. Decaisne. The author thinks that the use of this liquid as a drink ought to be abandoned.

DIARY

THURSDAY, MARCH 20.

ROYAL SOCIETY, at 8.30.—On the Distribution of Vertebrata in Relation to the Theory of Evolution: Dr. J. D. Macdonald.—On the Temperature at which Bacteria, Vibriones, and their supposed Germs are killed when immersed in Fluids or Exposed to Heat in a Moist State: Dr. Bastian.—Some New Theorems on the Motion of a Body about a Fixed Point: E. J. Routh.

SOCIETY OF ANTIQUARIES, at 8.30.—On the Hunnebedden of Drenthe in the Netherlands; Miscellaneous Antiquities: Governor Gregory.

ZOOLOGICAL SOCIETY, at 4.

LINNEAN SOCIETY, at 8.—On the "Take-all" Corn Disease of Australia: Dr. Mücke.

CHEMICAL SOCIETY, at 8.—On Iron and Steel: C. W. Siemens.

ROYAL INSTITUTION, at 3.—The Chemistry of Coal and its Products: A. V. Harcourt.

FRIDAY, MARCH 21.

ROYAL INSTITUTION, at 9.—On the Mythology of India: E. D. Lyon.

OLD CHANGE MICROSCOPICAL SOCIETY, at 6.30.—Annual Meeting.

ROYAL COLLEGE OF SURGEONS, at 4.—Extinct Mammals: Prof. Flower.

QUEKETT CLUB, at 8.—Conversazione.

SATURDAY, MARCH 22.

ROYAL INSTITUTION, at 3.—Darwin's Philosophy of Language: Max Müller.

SUNDAY, MARCH 23.

SUNDAY LECTURE SOCIETY, at 4.—The Theory of Stringed Musical Instruments: W. H. Stone.

MONDAY, MARCH 24.

GEOGRAPHICAL SOCIETY, at 8.30.—Notes on Khiva, and Routes leading to that country: Major-Gen. Sir H. C. Rawlinson, K.C.B., President.

LONDON INSTITUTION, at 4.—Fungoid Organisms: Prof. Thiselton Dyer.

ROYAL COLLEGE OF SURGEONS, at 4.—Extinct Mammals: Prof. Flower.

TUESDAY, MARCH 25.

ROYAL INSTITUTION, at 3.—Forces and Motions of the Body: Prof. Rutherford.

WEDNESDAY, MARCH 26.

ROYAL COLLEGE OF SURGEONS, at 4.—Extinct Mammals: Prof. Flower.

LONDON INSTITUTION, at 7.—Courts of Special Commercial Jurisdiction: N. H. Paterson.

SOCIETY OF ARTS, at 8.—On the Edible Starches of Commerce: P. L. Simmonds.

GEOLOGICAL SOCIETY, at 8.—Synopsis of the Younger Formations of New Zealand: Capt. F. W. Hutton.—On the Tree-ferns of the Coal-measures and their Relations to other living and fossil forms: W. Carruthers.—Notes on the Geology of Kazirûn, Persia: A. H. Schindler.

ARCHÆOLOGICAL ASSOCIATION, at 8.

ROYAL SOCIETY OF LITERATURE, at 8.30.—The Rhodian Law, and its connection with the Laws of Mediæval Europe: W. S. W. Vaux.

SOCIETY OF TELEGRAPH ENGINEERS, at 7.30.—On a new method of testing short lengths of highly Insulated Wire: Prof. Fleeming Jenkin.—On some points in connection with the India Government Telegraphs: W. E. Ayrton.

THURSDAY, MARCH 27.

ROYAL INSTITUTION, at 3.—Coal and its Products: A. V. Harcourt.

ROYAL SOCIETY, at 8.30.

CONTENTS

THURSDAY, MARCH 27, 1873

UNIVERSITY OARS

I.

WE have, not without motive, adopted the title of Dr. Morgan's book,*—so opportunely timed in its issue by its University publishers—as the heading for some considerations connected with the coming river "Derby;" for we propose to pass in review the leading features of the Hygienic value of these contests, which are claiming and receiving from year to year a growing importance, into which the book itself is an exhaustive inquiry.

Many a strong hand will tremble as it lifts this book for the first time, and many an eye will glisten with pleasure or grow dim with regret as it scans its lists and tables and reads the revelations made therein. For what do they tell—and tell too with a rare fulness and circumstantiality? All particulars as to the health, past and present, of the Oarsmen of both Universities who have rowed in the annual matches during the last forty years; that is, from the time of their organisation up to the last race rowed before the author began collecting the materials for his book. Year by year the crews are formed and the races rowed. Year by year the races pass and are forgotten, and the crews disappear and are *not* forgotten, although they may pass away from our sight. What has become of the old Oarsmen, the friends and favourites of other days? Are they "doing duty" in peaceful country parishes, or in crowded cities at home? or have they venturously gone forth to new lands to seek for more genial employments than the old one yields? What are they doing now? how fares it with them? and above all, have they suffered in heart or brain, in nerve or lung, from their old practice at the oar? The ample lists in Dr. Morgan's book, his own ably written pages, and the liberal extracts from his correspondents' answers to his queries — his correspondents being the oarsmen themselves and his queries being with sole reference to their health and bodily condition—tell us all: tell us where they are, what they are doing, what they did when with us and how they did it; and, in their own language, tell with characteristic frankness, and in words which we can still recognise as their old modes of expression, what they think and believe for or against their old favourite pastime. All write cheerily, and all to a man almost speak with prideful remembrance of their work at the oar, and the good they have derived from it. From Bengal writes McQueen:—"I am now a stout man, weighing fifteen stone, but able to be in the saddle all day without fatigue, or if necessary walk my ten or fifteen miles without any distress." We wonder if he still possess the same hand-power that he had in his youth? He had simply the strongest hand and wrist we have ever known, and never did we place our own palm in his without setting our teeth close, and subjecting the member when set free to a gentle manipulation, to restore circulation and revive feeling in its flattened digits. His was the true Herculean build. Nind writes from Queensland on "Since taking my degree in 1855 my constitution has been put to the test in many climates, for I have lived in Canada, on the west coast of America, and in Australia, and I can safely aver that I never have in trying circumstances found a failure of physical power; and that when hard pressed by fatigue and want of food, the recollection of the endurance developed by rowing and other athletics gave me fresh spirit and encouragement." And yet Nind was not naturally a powerful man. His frame was the very antithesis to that of McQueen. Those who remember him as he first came to the University will recall his exquisitely moulded features, almost feminine in their softness and sweetness of expression. Schneider writes from New Zealand:—"I may state that so far as I am concerned, I am able to discover no particular symptoms either good, bad, or indifferent specially attributable to rowing. . . . . I now come to what I believe to be the chief if not the only real danger attendant upon Boat-Racing, and that is the violent strain upon the action of the heart caused by rowing a rapid stroke and exerting every energy to maintain the same to the end of the race."

Who among us could argue the matter more wisely? These are bright and pleasant pictures, but like all other pictures, they have their dark side. In the lists of Oarsmen certain names are printed in italics—not many, thank God!—a small percentage only. These are they who have rowed out their life-race; who have for ever passed out from their period of training and of trial. They rise before our mind's eye as we first knew them. Brewster's magnificent form towering half a head above his stalwart shipmates. Men are all wise after the events; and we hear now of those who always doubted his real strength and stamina, and point to his untimely end as evidence of their own penetration. "Invalided from his regiment, caught cold by returning wet from a Brighton Volunteer Review: died from its effects." Polehampton, the chivalrous, the gentle, the brave! "Decorated while at college with the Royal Humane Society's Medal for saving a companion from drowning at his own imminent peril. Shot through the body at Lucknow — and died of cholera when attending to his comrades stricken by the same malady." The very career he would have marked out for himself, had it been left to his hand to trace it! Hughes, the accomplished, the frank, the manly—the very nature that, speaking in our love and in our pride, we emphatically style the beau-ideal of an English gentleman—"died last year of inflammation of the lungs." Here our personal reminiscences of old oarsmen must cease.

For many a long year strange tales of the risks and dangers of rowing, or rather of boat-racing, have had a floating existence in the Universities, and gaining strength and circumstantiality by time and repetition, have extended to wider circles. While the old tales lived and held their own, other and more startling legends sprang up, and also grew into importance, legends so alarming, and related with such circumstantial detail, that the most sceptical began to think that "there must be something in it." Whole crews, it was stated, had been swept off in a few brief years by their terrible struggles and efforts at the oar. This feeling of uneasiness, if not of absolute alarm, attained a sort of climax a few years ago by the letters of an eminent surgeon, published in the *Times*.

* "University Oars." By John Ed. Morgan, M.A. Oxon, F.R.C.P. (Macmillan, 1873.)

For reasons which seemed to his professional judgment sufficient, he took the side of the alarmists, and pronounced an opinion, strongly expressed, against boat-racing as now practised. These letters were answered with more or less ability by votaries of the oar, men then actively engaged in rowing, or who had recently been so. The controversy lasted for some time, and at last rather died out, or was allowed to drop, than brought to any satisfactory conclusion by the arguments or proofs advanced on either side. By the opponents of boat-racing the case was opened rather unguardedly by statements requiring a stronger array of facts than could be brought to support them when the call for proofs was made; by its defenders was met by the somewhat blunt rejoinder, "You don't know anything about it; you never lifted an oar in your life." The former forgetting that there is nothing so difficult to overcome as enthusiasm, *esprit de corps*, and, perhaps, prejudice; the latter forgetting that the effects of certain modes of exertion on certain organs and tissues of the human body may be sagely divined by a skilful and experienced physician or surgeon, without his ever having in his own person practically undergone such exertion.

As we have said, the argument dropped rather than was brought to any satisfactory conclusion, and if each side did not claim the victory, each stoutly denied that the other had won. Unto this day do we hear alarms sounded with reference to these races, again does paterfamilias feel nervous qualms at the intelligence that his son has betaken himself to the river. Again do non-rowing men console themselves for the want of river distinctions by the thought of their exemption from its risks and liabilities, and again do rowing men enjoy the *éclat* of having greatly dared for the reputation of their Colleges and University, with the secret conviction and comfort that the dangers they have run have been very slight indeed.

It was to close this open question for ever, and settle once for all this standing dispute which has many scientific aspects of great interest, that Dr. Morgan undertook the present work, recognising evidently to the full the standpoint selected by the disputants in the controversy, the one, their practical knowledge as experienced oarsmen, the other, his theoretical knowledge as a scientific surgeon; for, as the author informs us, his qualifications for the task are twofold:—

"As a physician to a large hospital, I have necessarily enjoyed large opportunities of gaining an insight into the laws which regulate our health, while my rowing experience began at Shrewsbury (where I spent many a pleasant hour on the Severn), and was matured at University College, Oxford, where I was for three years Captain of the John +, a boat which has often played a prominent part in the struggles on the Isis, and which has served as the training school for no fewer than ten of the crews which during the last thirty years have won the University Fours."

These qualifications certainly seem adequate to the task, and the plan pursued by Dr. Morgan also seems the best possible, albeit entailing enormous labour on, and demanding vast patience from, him. This plan was simply to institute a strict and exhaustive search after all the men who have rowed in these inter-University contests; to track them, as it were, to whatever part of the world they may have gone: this done, to get their own written testimony, if alive, and that of their friends, if dead, as to whether the part they played in these contests entailed any after evil results upon their constitutions and frames, and (if any) their nature and extent.

Considering that more than forty years have elapsed since the commencement of these friendly contests, and that between the years 1829-1869 twenty-six races have been rowed, giving for the crews of both Universities, and allowing for men who have rowed in more than one race, the gross number of 294 men, the task was a formidable one; but, we must add, has been as ably conducted to its conclusion as it was resolutely undertaken. The author has ascertained that out of these 294 men 245 are still living—39 having died: the time of their death and the ailment of which they died are carefully given by the author, and to this point we will return. He next tabulates the following results elicited by his inquiries:—

Benefited by rowing . . .	115
Uninjured „ . . .	162
Injured „ . . .	17

The *benefits* derived are somewhat vaguely stated, as indeed was to be expected when almost the only benefits that could be reasonably derived from such pursuits would be of a *general* nature; such as increase of strength and stamina, increase of energy to undertake, increase of power to undergo, physical exertion; increase of fortitude to encounter and to submit to trials and privations and disappointments. A goodly list of benefits when critically examined. *The uninjured* are those who in their replies to the author's queries state *negatively* the results of rowing upon their constitutions and frames; or, in the author's language, who merely say in general terms "that they never felt any inconvenience from rowing;" while the *injured* are they who state with less or more distinctness that their exertions proved harmful.

We must confess that this last item in the bill, the 17 injured, is at first sight a little startling, and so it must, we think, have appeared to the author, for he very carefully and minutely examines the cases so recorded, and some, we think, successfully dismisses as unreal; while others, we fear it must be candidly avowed, must remain as *bonâ fide* instances of injury. But is this a matter to be wondered at when the number of men who had been so engaged is taken into consideration? Is there any other pastime or pursuit in which grown men can take part, such as draws forth at the same time their bodily power and keenest emulations, which will yield a smaller percentage of evil? Would the hunting-field, would the foot-ball field, or even the cricket-field, if closely scrutinised?

The author tells us that during his inquiries on this subject he has written over two thousand letters. We can well believe it, knowing how unwilling many men are to reply to personal inquiries, and specially so when the inquirer asks after personal ailments. He has not however done himself justice in not giving us in his book a specimen of his letters addressed to his scattered correspondents; for in all cases of dispute, and contested evidence, it is always a matter of objection if the question as put indicates or leads up to the sort of answer desired; and when, as has been already said, scepticism on one side and *esprit de corps* on the other so strongly prevails, doubts may be entertained of the accuracy of some of

the statements made in the correspondents' replies. But we think that it will be admitted that as a whole those replies are eminently satisfactory.

A circumstance quite noteworthy, however, strikes the reader who scrutinises the lists as tabulated recording the instances of *injured*, and we would be glad to hear some explanation or interpretation of what at present seems inexplicable. Thus out of the first six races only three men are recorded as injured, while out of the next four races nine men are so recorded, five being mentioned in one race—that of 1845—and two more in the race of the following year. Again occurs a period of comparative immunity from injury, only one case being instanced in the next seven races. Once more is the order changed, for in the following four races four men are recorded as injured, while in the five remaining races of the series no injury whatever seems to have been sustained. The author does not seem to have instituted any inquiry on this point, yet surely it is one worth investigation, seeing that it is this very matter of liability to injury which is the sole subject of dispute, to settle which is the avowed object of his book. Was this injury-rate affected by the mode of training of the crews, the physical calibre or age of the individual men composing them, by the severity of the contest itself, or by the character of the season when the men trained and rowed?

ARCHIBALD MACLAREN

THOMSON & TAIT'S NATURAL PHILOSOPHY

Elements of Natural Philosophy. By Professors Sir W. Thomson and P. G. Tait. Clarendon Press Series. (Macmillan and Co., 1873.)

NATURAL Philosophy, which is the good old English name for what is now called Physical Science, has been long taught in two very different ways. One method is to begin by giving the student a thorough training in pure mathematics, so that when dynamical relations are afterwards presented to him in the form of mathematical equations, he at once appreciates the language, if not the ideas, of the new subject. The progress of science, according to this method, consists in bringing the different branches of science in succession under the power of the calculus. When this has been done for any particular science, it becomes in the estimation of the mathematician like an Alpine peak which has been scaled, retaining little to reward original explorers, though perhaps still of some use, as furnishing occupation to professional guides.

The other method of diffusing physical science is to render the senses familiar with physical phenomena, and the ear with the language of science, till the student becomes at length able both to perform and to describe experiments of his own. The investigator of this type is in no danger of having no more worlds to conquer, for he can always go back to his former measurements, and carry them forward to another place of decimals.

Each of these types of men of science is of service in the great work of subduing the earth to our use, but neither of them can fully accomplish the still greater work of strengthening their reason and developing new powers of thought. The pure mathematician endeavours to transfer the actual effort of thought from the natural phenomena to the symbols of his equations, and the pure experimentalist is apt to spend so much of his mental energy on matters of detail and calculation, that he has hardly any left for the higher forms of thought. Both of them are allowing themselves to acquire an unfruitful familiarity with the facts of nature, without taking advantage of the opportunity of awakening those powers of thought which each fresh revelation of nature is fitted to call forth.

There is, however, a third method of cultivating physical science, in which each department in turn is regarded, not merely as a collection of facts to be co-ordinated by means of the formulæ laid up in store by the pure mathematicians, but as itself a new mathesis by which new ideas may be developed.

Every science must have its fundamental ideas—modes of thought by which the process of our minds is brought into the most complete harmony with the process of nature—and these ideas have not attained their most perfect form as long as they are clothed with the imagery, not of the phenomena of the science itself, but of the machinery with which mathematicians have been accustomed to work problems about pure quantities.

Poinsôt has pointed out several of his dynamical investigations as instances of the advantage of keeping before the mind the things themselves rather than arbitrary symbols of them; and the mastery which Gauss displayed over every subject which he handled is, as he said himself, due to the fact that he never allowed himself to make a single step, without forming a distinct idea of the result of that step.

The book before us shows that the Professors of Natural Philosophy at Glasgow and Edinburgh have adopted this third method of diffusing physical science. It appears from their preface that it has been since 1863 a text book in their classes, and that it is designed for use in schools and in the junior classes in Universities. The book is therefore primarily intended for students whose mathematical training has not been carried beyond the most elementary stage.

The matter of the book however bears but small resemblance to that of the treatises usually put into the hands of such students. We are very soon introduced to the combination of harmonic motions, to irratational strains, to Hamilton's characteristic function, &c., and in every case the reasoning is conducted by means of dynamical ideas, and not by making use of the analysis of pure quantity.

The student, if he has the opportunity of continuing his mathematical studies, may do so with greater relish when he is able to see in the mathematical equations the symbols of ideas which have been already presented to his mind in the more vivid colouring of dynamical phenomena. The differential calculus, for example, is at once recognised as the method of reasoning applicable to quantities in a state of continuous change. This is Newton's conception of Fluxions, and all attempts to banish the ideas of time and motion from the mind must fail, since continuity cannot be conceived by us except by following in imagination the course of a point which continues to exist while it moves in space.

The arrangement of the book differs from that which has hitherto been adopted in text-books. It has been

usual to begin with those parts of the subject in which the idea of change, though implicitly involved in the very conception of force, is not explicitly developed so as to bring into view the different configurations successively assumed by the system. For this reason, the first place has generally been assigned to the doctrine of the equilibrium of forces and the equivalence of systems of forces. The science of pure statics, as thus set forth, is conversant with the relations of forces and of systems of forces to each other, and takes no account of the nature of the material systems to which they may be applied, or whether these systems are at rest or in motion. The concrete illustrations usually given relate to systems of forces in equilibrium, acting on bodies at rest, but the equilibrium of the forces is established by reasoning which has nothing to do with the nature of the body, or with its being at rest.

The practical reason for beginning with statics seems to be that the student is not supposed capable of following the changes of configuration which take place in moving systems. He is expected, however, to be able to follow trains of reasoning about forces, the idea of which can never be acquired apart from that of motion, and which can only be thought of apart from motion by a process of abstraction.

Profs. Thomson and Tait, on the contrary, begin with kinematics, the science of mere motion considered apart from the nature of the moving body and the causes which produce its motion. This science differs from geometry only by the explicit introduction of the idea of time as a measurable quantity. (The idea of time as a mere sequence of ideas is as necessary in geometry as in every other department of thought.) Hence kinematics, as involving the smallest number of fundamental ideas, has a metaphysical precedence over statics, which involves the idea of force, which in its turn implies the idea of matter as well as that of motion.

In kinematics, the conception of displacement comes before that of velocity, which is the rate of displacement. And here we cannot but regret that the authors, one of whom at least is an ardent disciple of Hamilton, have not at once pointed out that every displacement is a vector, and taken the opportunity of explaining the addition of vectors as a process, which, applied primarily to displacements, is equally applicable to velocities, or the rates of change of displacement, and to accelerations, or the rates of change of velocities. For it is only in this way that the method of Newton, to which we are glad to see that our authors have reverted, can be fully understood, and the "parallelogram of forces" deduced from the "parallelogram of velocities." Another conception of Hamilton's, however, that of the hodograph, is early introduced and employed with great effect. The fundamental idea of the hodograph is the same as that of vectors in general. The velocity of a body, being a vector, is defined by its magnitude and direction, so that velocities may be represented by straight lines, and these straight lines may be moved parallel to themselves into whatever position is most suitable for exhibiting their geometrical relations, as for instance in the hodograph they are all drawn from one point. The same idea is made use of in the theorems of the "triangle" and the "polygon" of forces, and in the more general method of "diagrams of stress," in which the lines which represent the stresses are drawn, not in the positions in which they actually exist, but in those positions which most fully exhibit their geometrical relations. We are sorry that a certain amount of slight is thrown on these methods in § 411, where a different proposition is called the *true* triangle of forces.

It is when a writer proceeds to set forth the first principle of dynamics that his true character as a sound thinker or otherwise becomes conspicuous. And here we are glad to see that the authors follow Newton, whose Leges Motûs, more perhaps than any other part of his great work, exhibit the unimproveable completeness of that mind without a flaw.

We would particularly recommend to writers on philosophy, first to deduce from the best philosophical data at their command a definition of equal intervals of time, and then to turn to § 212, where such a definition is given as a logical conversion of Newton's First Law.

But it is in the exposition of the Third Law, which affirms that the actions between bodies are mutual, that our authors have brought to light a doctrine, which, though clearly stated by Newton, remained unknown to generations of students and commentators, and even when acknowledged by the whole scientific world was not known to be contained in a paragraph of the *Principia* till it was pointed out by our authors in an article on "Energy" in *Good Words*, October 1862.

Our limits forbid us from following the authors as they carry the student through the theories of varying action, kinetic force, electric images, and elastic solids. We can only express our sympathy with the efforts of men, thoroughly conversant with all that mathematicians have achieved, to divest scientific truths of that symbolic language in which the mathematicians have left them, and to clothe them in words, developed by legitimate methods from our mother tongue, but rendered precise by clear definitions, and familiar by well-rounded statements.

Mathematicians may flatter themselves that they possess new ideas which mere human language is as yet unable to express. Let them make the effort to express these ideas in appropriate words without the aid of symbols, and if they succeed they will not only lay us laymen under a lasting obligation, but, we venture to say, they will find themselves very much enlightened during the process, and will even be doubtful whether the ideas as expressed in symbols had ever quite found their way out of the equations into their minds.

TYNDALL'S FORMS OF WATER

The forms of Water in Clouds and Rivers, Ice, and Glaciers. By John Tyndall, LL.D., F.R.S. (London: H. S. King & Co.)

WHATEVER comes from Dr. Tyndall's pen is sure to be vivid and clear. The present little volume forms no exception to this rule. It seems to have been composed partly in the form of popular lectures and partly as a sort of journal of a visit last year to the author's favourite holiday haunts among the Swiss glaciers. Very readable, it nevertheless betrays this composite origin, and wears more the aspect of a piece of book-making than

probably its author himself could have wished. A wrong impression of the subject is created by the title, which though singularly happy in itself does not fairly describe the contents of the book. Such a title suggests an accurate and luminous discussion of the phenomena of evaporation and condensation, the growth and movements and disappearances of mists and clouds, the formation and distribution of rain and the laws regulating the rainfall over the globe, the meaning of frost, the birth and history of hail and snow, the circulation of water over the land with the ways and workings of brook, stream, and river, from mountain-peak to sea-shore, the architecture and the functions of snow-fields, glaciers, and icebergs—in short a kind of scientific poem, dedicated to the glory of that grand old element—water. Dr. Tyndall could write such a poem better than most men, and indeed it was with the expectation that he had attempted it that we opened this last volume of his. Out of the 192 pages 28 are devoted to clouds, rains, rivers, waves of light and heat, oceanic distillation and mountain condensers. The rest treat wholly of ice. So that if we may judge by the relative space devoted to the different forms of water, ice must be six times more important than all the rest put together. A less ambitious title, such as its author could readily suggest, descriptive of the fact that the book is a record of work, intellectual and corporeal, among the Swiss glaciers, would prevent the feeling of disappointment with which many a reader has no doubt come to the last page.

Dr. Tyndall did not intend, we suppose, that his book should be regarded in any other light than as a popular exposition of his subject, and would probably disclaim any place for it as a contribution of new facts and reasonings to our knowledge of glaciers. His narratives of last year's climbings and observations read very much like those of older ones with which he has already made us familiar. They are pleasantly written, and will convey to a reader, who has never seen a glacier, a picturesque notion of what he has missed. But surely it was not necessary to rake up again the Forbes-Rendu controversy, nor to renew the claims of Agassiz and Guyot. We could have wished, too, that while alluding to Mr. Mathews and other recent observers on ice-structure the writer had taken some notice of the attack upon his own theory by Canon Mosely and Mr. Croll.

OUR BOOK SHELF

Die Anwendung Des Spectralapparate von Dr. K. Vierordt. (Tübingen: H. Laupp, 1873.)

DR. VIERORDT has been endeavouring to found a quantitative spectrum analysis for bodies giving an absorption spectrum. His method consists in the use of a slit divided horizontally into two parts; one of these is adjusted to a certain width; the solution whose absorption is to be examined is placed opposite this, and in front of the other half is placed another solution of the same body but of a different strength, and the slit is then narrowed or widened as the solution is stronger or weaker until the absorption is the same in both halves of the spectrum. The width of the latter slit is then read off. By using a number of solutions of strengths varying decimally from the weakest possible to the strongest through which light will pass, curves are obtained and a solution of unknown strength can then be interpolated in the curve and its value ascertained. The solutions to be examined are, of course, kept at a constant thickness. As the relation between the concentration of the solution and its coefficient of the absorption of light only remains constant within certain limits, solutions of the necessary dilution have to be employed and unknown solutions must be diluted to this point: the value is then found by calculation.

Tables for calculations of various kinds required are given, and the memoir is illustrated with lithographs of the working details of the divided slit. A number of specimen curves are also given. The memoir is well worthy the attention of all who have to estimate the strength of colouring matter.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Existence of Man in the Miocene

I HAVE received a letter from Mr. Edmund Calvert, in which he informs me that his brother, Mr. Frank Calvert, has recently discovered, near the Dardanelles, what he regards as conclusive evidence of the existence of man during the Miocene period. Mr. Calvert had previously sent me some drawings of bones and shells from the strata in question, which Mr. Busk and Mr. Gwyn Jeffreys were good enough to examine for me. He has now met with a fragment of a bone, probably belonging either to the Dinotherium or a Mastodon, on the convex side of which is engraved a representation of a horned quadruped, "with arched neck, lozenge-shaped chest, long body, straight fore legs, and broad feet." There are also, he says, traces of seven or eight other figures, which, however, are nearly obliterated. He informs me that in the same stratum he has also found a flint flake, and several bones broken as if for the extraction of marrow.

This discovery would not only prove the existence of man in Miocene times, but of man who had already made some progress, at least, in art. Mr. Calvert assures me that he feels no doubt whatever as to the geological age of the stratum from which these specimens were obtained.

Of course I am not in a position myself to express any opinion on the subject; but I am sure that the statements of so competent an observer as Mr. Calvert will interest your readers.

High Elms, March 23 JOHN LUBBOCK

Adaptation to External Conditions

THE curious modification of adaptation to external conditions in the case of the *Salamandra atra*, which I have more than once brought under the notice of naturalists, but which I myself first noticed under the direction of Prof. von Siebold, has been cited by Mr. Darwin ("Origin of Species," 4th Ed. p. 534) in confirmation of his views. I revert to it now for the sake of its illustration of a new and striking observation, which has excited the incredulity of several eminent naturalists in France—an incredulity, we may suppose, founded on their ignorance of the previous observation. The fact to which I called attention was this: The ordinary salamander, or Newt, is born in the water as a tadpole, and in the water it completes its metamorphosis. But the *Salamandra atra*, living high up in the mountains, with no pools in which to pass its tadpole existence, is born on the land, a completely formed animal; that is to say it passes through the tadpole stage while still within its mother's body. I have taken it from the gravid female in this tadpole state, and placed it in water, wherein it swam as if that were its natal element.

In the *Revue Scientifique*, No. 37, there has just appeared a brief account of some observations made by M. Baray at Guadeloupe, from which it appears that the frogs, having in that volcanic island no marshes nor pools suitable for the early tadpoles, have adapted themselves to these conditions by passing through

all the tadpole stages of metamorphosis while still in the egg. All these stages have been observed by M. Baray; and whoever is familiar with the evolution of the ordinary tadpole before it quits the egg, will see that M. Baray has observed only a modified form of the well-known process. The Guadeloupe frog is born as a frog, not as a tadpole; and this, paradoxical as it may seem to some naturalists who cannot dismiss traditional conceptions, is even less remarkable than the case of the *Salamandra atra*, because it is only an extension of the period of incubation, whereas with the salamander it is the substitution of viviparity for oviparity. How the presence of water leads to an acceleration of the birth, or the absence of water leads to its retardation, is an interesting point for investigation; whether retarded or accelerated, the finally-acquired structure is the same.

The Priory, March 22 GEORGE HENRY LEWES

Anticipations of Natural Philosophy

MAUPERTUIS

HAVING lately had occasion to examine the works of Maupertuis I, like Prof. Jevons, was struck by meeting with anticipatory glimpses of the modern theory of Natural Selection. The passage, given almost word for word by Lord Bolingbroke in the quotation made by Prof. Jevons, occurs somewhat incidentally in two parts of Maupertuis' writings; in the memoir alluded to ("Les Loix du Mouvement et du Repos, déduites d'un principe métaphysique"); and in the "Essay de Cosmologie," into which the memoir was expanded five years later (1751). In both these works Maupertuis is chiefly concerned with establishing his well-known metaphysico-mechanical principle of "The Least Action" ("La moindre Quantité d'Action"); and with deducing therefrom proof of the existence of God. But the doctrine of "The Survival of the Fittest" is more clearly discernible, and more than incidentally referred to, in his small physiological treatise, "Venus physique" (Œuvres, tome ii. ed. 1756). The whole of this work is not wanting in interest, but as bearing specially on the subject in question, I would mention the third, fifth, and last chapters of the second part. Chapter III. is entitled "Production de nouvelles especes." In it the most pronounced passage is perhaps the following: "Mais la sage Nature, par le dégoût qu'elle a inspiré pour ces défauts, n'a pas voulu qu'ils se perpetuassent; chaque père, chaque mère fait de son mieux pour les éteindre; les beautés sont plus sûrement héréditaires; la taille, et la jambe, que nous admirons, sont l'ouvrage de plusieurs générations, où l'on s'est appliqué à les former." Chapter V., called an "Essay d'explication des phénomènes précédents," is an attempt to explain the physiological processes at work in the preservation of the best types, and in the production of new forms. On the efficacy of these processes the author says: "L'expérience pourroit, peut-être, éclaircir ce point; si l'on essayoit pendant longtemps de mutiler quelques animaux de génération en génération, peut-être verroit-on les parties rétranchées, diminuer peu à peu; peut-être verroit-on les à la fin s'anéantir." The last chapter contains a summary of the whole work, and a number of "Doutes et Questions," propounded by the author. In one of these he asks, "Cet instinct des animaux, qui leur fait rechercher ce qui leur convient, et fuir ce qui leur nuit, n'appartient-il point aux plus petites parties dont l'animal est formé?" In another question Maupertuis puts forward a bold hypothesis as to the influence which the decomposed material of the dead animal organism might exercise upon plants, and through them upon the structure and character of the living organism.

In his *Système de la Nature* also (Œuvres, tom. ii. ed. 1756), Maupertuis combats the special creation theory of the origin of species, and advocates a doctrine, which may be called Natural Selection, the selective principle being placed in the ultimate elements of both organic and inorganic substances, of which elements "la perception est une propriété essentielle," and which "doués d'intelligence s'arrangent et s'unissent pour remplir les vues du Créateur."

Such are a few of the glimpses to be met with in the French philosopher, of the modern doctrine of Darwin and Spencer. Similar ones may not improbably be found elsewhere, but such "resultless tendencies," as the course of events has proved them to be, can in no degree detract from the merit and originality of those who have made of Natural Selection a well-substantiated and homogeneous theory. W. H. BREWER

Grace's Road, Camberwell, March 10

EMPEDOCLES

ON reading Prof. W. Stanley Jevons' interesting letter in this week's NATURE, I referred to my note-book, and found the following quotation, under the title of "Natural Selection," which shows that the opinion of Maupertuis is at least as old as Empedocles.—"Cette dernière opinion sert á expliquer les Idées d'Empédocle sur la production des animaux par des causes accidentelles. L'attraction et la répulsion des élémens donnèrent naissance dans les commencemens et par le seul effet du hasard, à des têtes sans cou, à des jambes sans corps, à des animaux moitié bœufs et moitié hommes, en un mot, à une foule de monstrés semblances. Parmi tous ces êtres, les uns étaient construits de manière qu'ils semblaient êtres doués de l'intelligence: ceux-là conservèrent la vie, et propagèrent leur espèce, mais ceux auxquels l'organe de la vie manquait, retombèrent dans le chaos, d'ou ils étaient sortis." ("Histoire de la Medécine," par Kurt Sprengel, vol. i. p. 249.) Sprengel gives the following references:—Aristotle, Physic. Lib. ii., c. 4, p. 465., c. 8, p. 470. Owing to my distance from a public library I have not hitherto had an opportunity of referring to Aristotle; but as Prof. Jevons is more favourably circumstanced, I hope he will consult the original, and if he finds anything which throws further light upon this interesting question, that he will report it to your readers.

Although, as Prof. Jevons remarks, the introduction of the notion of *chance* is erroneous, the speculation shows how thoroughly the Greek Atomists had banished from their explanations of phenomena all reference to first and final causes, anticipating in this respect the modern conception of science. I cannot deny myself the pleasure of quoting the weighty judgment of Bacon upon this point:- "And therefore the natural philosophies of Democritus and others," says Bacon, "who allow no God or mind in the frame of things, but attribute the structure of the universe to infinite essays and trials of nature, or what they call fate or fortune, and assigned the causes of particular things to the necessity of matter without any intermixture of final causes, seem, so far as we can judge from the remains of their philosophy, much more solid, and to have gone deeper into nature, with regard to physical causes, than the philosophy of Aristotle or Plato; and this only because they never meddled with final causes, which the others were perpetually inculcating." (Advancement of Learning, Book iii. chap. iv.)

Waterfoot, March 8 JAMES ROSS

ARISTOTLE

IT is interesting, as Mr. Jevons says, to observe such traces as are to be found in history of theories more or less anticipating the principle of natural selection. But if the instance he cites from Maupertuis fairly represents the last century in this matter, it is chiefly of interest as showing what a little way it is possible to travel on certain roads in twenty-two centuries: for Aristotle discusses the same theory in his "Physics" (ii. 8), and appears to attribute it to Empedocles. "It may be a question," he says, "whether physiological effects which seem to be due to final causes are not really accidental. An organism survived, we may suppose, if it happened to be as a whole constituted in a suitable manner; that is, in a manner in which it would have been constituted by design; organisms otherwise constituted perished and perish still, like the βουγενῆ ἀνδρόπρωρα of Empedocles." Now, except that his monsters are certainly not quite so monstrous, I do not see that the "Flattener of the Earth" gets beyond that. At any rate he lags behind Lucretius, who adopts the same theory of "discriminative destruction" (v. 837–877), but applies it, as Mr. Munro points out (on line 855), not merely to monsters but to "regularly organised creatures," either not so gifted as to protect themselves or not so valuable as to be protected by man.

This is, as far as it goes, a theory of natural selection. It is a theory of the survival of the fit, absolutely; but not being a theory of the preponderant survival of the fitter, and not taking adequate account of inheritance, it is not a theory of evolution. Indeed, though Lucretius recognised a constant change in the conditioning circumstances, and therefore in the organisms conditioned (828–836), it was to account for the stability of species that be called in natural selection and not to give a clue to the laws of their variation. That is the direction in which there must have been most room for progress; and traces of such progress may be to be found. Has Mr. Jevons tried Gassendi? C. J. MONRO

Hadley, Middlesex

Fossil Cryptogams *

I do not propose at present to controvert in detail all the positions taken up by my friend Prof. McNab in his brief communication to your pages on "Fossil Cryptogams" (vol. vii. p. 267), because the time has not yet arrived for doing so. Much more detailed information respecting the subject which yet awaits publication must be had before it can be discussed in a satisfactory manner. I merely wish to avoid leaving the impression, by my silence, that I either admit his supposed facts or accept his inferences. When his paper, to which he refers, was read in Edinburgh, specimens of sections of Calamites of various ages were sent down by me for the purpose of being exhibited to the Botanical Society. This was done by Prof. Dickson, who at the same time expressed his preference for my views over those of Dr. McNab, as is stated in the officially published notice of the meeting in question. Since then I have received a kind letter from Dr. Balfour, who has carefully examined the specimens referred to, and who also expresses a similar conviction. I think that I have unmistakeable proof of the circumferential growth of Calamites, which Dr. Macnab denies, in specimens of large size, and in which the exogenous zone is of great thickness.

Prof. McNab speaks of "the moist nature of the soil in which the Calamites must have grown," as probably causing a different mode of growth in them, to that "circumferential" one which he admits has probably taken place in Lepidodendra, Sigillariæ, and Dictyoxylons; but I beg to suggest that we have no reasons for thinking otherwise than that these plants grew side by side, and under precisely the same physical conditions, hence the "moist soil" of my friend is an assumption. This close association of Calamites with Sigillariæ was demonstrated and commented upon by Mr. Binney many years ago. Dr. McNab further separates Lepidodendron from Sigillaria and Stigmaria, placing them in different groups. When he receives my third memoir in the Philosophical Transactions (which is printed but not yet circulated), he will see how utterly this plan of procedure is opposed to the facts. I contend that Sigillariæ are virtually Lepidodendra, and that Stigmaria is equally the root of both. As to the location of my old, but now abandoned genus, Dictyoxylon, the more I study it the less I feel competent to fix its true place amongst the Cryptogams. But notwithstanding Dr. McNab's idea as to its coniferous affinities, I venture to affirm, from a prolonged study of a cabinet full of specimens, that its woody axis is not one bit more exogenous than those of Calamites and of *matured* Lepidodendra. The fact is that whatever the vessels of these various exogenous woody zones signify, they must stand or fall together. They are either all ligneous or they are all cortical. I think that my forthcoming illustrations of the *bark-structures* amongst the Burntisland Lepidodendra, as well as of our Lancashire specimens, will show that all the elements which Dr. McNab finds in Lycopodium Chamæcyparissus are present, in their proper places, the schlerenchyma of the hypoderm being especially well represented, yet it is precisely this hypoderm with which Dr. McNab believes my exogenous layer to correspond. There is one if not two distinct layers of cortical parenchyma between this schlerenchymatous layer and my ligneous zone, which latter is so magnificently represented in these plants.

The intimate structure of these latter layers, whether we regard the forms and arrangements of the entire woody wedges or that of their component tissues, is so identical in the two cases of Calamites and Lepidodendra, that an active imagination alone can make the one axial and ligneous, and the other cortical. Dr. McNab draws a distinction between vessels representing ("feebly") the fibro-vascular bundles of the living Equisetums, in the Calamites, and the more external portions of each woody wedge, which he regards as representing the hypodermal schlerenchyma of Mettenius. I unhesitatingly avow that there is no ground whatever for this arbitrary separation. He is putting asunder things which have been joined together from the beginning of time. The tissues in question are as identical in their structure as they are uninterruptedly continuous in their arrangement.

Whilst I am thus opposed to Dr. McNab both on questions of fact and of inference, I feel obliged to him for calling my attention to this possible explanation of the facts, even though after a careful study of his views I feel constrained to reject them so far as the interpretation of Calamites are concerned. On the questions relating to Meristem growths, we are much nearer to mutual agreement, and I accept thankfully his admission of the coniferous affinities of Dictyoxylon, not because I am prepared to recognise any specially close coniferous relationships, but because Dr. McNab's idea necessarily involves an admission of the existence of exogenous features in these plants; yet I contend that the Dictyoxylons are neither more coniferous nor more exogenous than most of the other Cryptogamic carboniferous stems which exhibit equally strong proofs of a similar exogenous growth. But I again repeat that we shall not be in a position to grapple philosophically with these problems until all the results of my prolonged researches are published. This is being accomplished as rapidly as my limited leisure admits of. When completed, I shall be quite prepared to enter, if necessary, and in a friendly spirit, upon the entire controversy.

Leaf Arrangement

After reading Dr. Airy's paper on Phyllotaxis (Nature, vol. vii. p. 343), I cannot see that we are at all nearer than before, any satisfactory explanation as to the inherent cause of it. Let the question be put thus:—If we can conceive, as all will admit, the possibility of leaves being scattered anyhow along a branch, why are they not so, but in some strictly mathematical order? Any disturbance in that order is usually so slight and trivial (due apparently in part to the *conical* nature of the axis, and unequal growth or slight twists; and which thereby cause certain leaves to assume slightly wrong positions), that it does not destroy the fact that they absolutely are arranged, and can be represented, *mathematically*.

In my paper on the angular divergences of the Jerusalem artichoke (Linnean Trans. vol. xxvi. p. 647), I pointed out that two questions might represent all that is required to be solved. (1) That if a leaf be selected as No. 1, then No. 2 lies within a certain arc, viz.:—120°—180° from No. 1, for the ordinary series of fractions, and which it does not transgress—why is this? (2) If we allow that arc—why does the second leaf not assume *any* spot, but is rigidly confined to a certain angular distance from the first?

I cannot think with Dr. Airy that "the way in which all the spiral orders may have been derived from one original order [was] by means of different degrees of twist in the axis." For if we take a piece of round elastic as he describes, with balls fixed according to some spiral arrangement—say $\frac{2}{5}$—then the successive balls will lie at an angular distance of 144°; and if No. 1 be fixed and we twist the indiarubber at No. 2, we may cause it to make a complete rotation if we choose.

If, now, his idea of "twist" be admitted as a *vera causa* of phyllotaxis, we may ask, *what causes the twist to be just so much and no more as to make* No. 2 *pass through* 9° (the angular divergence of $\frac{3}{8}$ being 135), so as to pass into the next $\frac{3}{8}$ arrangement? To say that some such point is a "position of maximum stability" seems to me to give a fictitious importance to the idea of twist, for the expression conveys no really explanatory meaning at all.

Again, to admit that it does not accurately hit the right place, and is in consequence more like Nature, is equally delusive, for Nature is quite accurate enough to be represented mathematically, whereas the positions taken up by the balls must be arbitrary, or at least in proportion to the twist given by the hand—a perfectly arbitrary force? Moreover he appears to overlook the fact that if an axis becomes twisted the *fibres* will be twisted also, but they are not so; the elastic band he adopts would, if it were a pliant shoot, contort the vessels and wood fibres, a condition not obtaining in nature.

Nor can I agree with him in deducing all the members of the series from $\frac{1}{2}$. My experience leads me to infer they are derived from *opposite* leaves, such as one finds in the cotyledons. In the Jerusalem artichoke opposite leaves are frequently succeeded by $\frac{2}{5}$; and this is obtained by the pair of leaves, next above the strictly opposite pair, converging to one side, the next pair do so still more, when it will be found that the $\frac{2}{5}$ arrangement will be henceforth established; the internodes having become more and more developed at the same time.

I strongly suspect the original arrangement to have been whorled and quincuncial. This is at least very abundant, if not universal, in coal plants. The whorls may have subsequently become reduced to fours, threes, and twos or decussate. We see this tendency to symmetrical reduction in many existing plants, *e.g.* stamens and carpels of *Cruciferæ*: *Circæa* as com-

pared with *Epilobium*; the stamens of *Geranium* as compared with *Erodium*. Where the reduction has been unsymmetrical, I suspect it has been due to insect adaptation: as in di-dynamous stamens.

As soon as decussate leaves are secured, then we possess the basis for all ordinary leaf-arrangements.

Dr. Airy alludes to non-existing orders, $\frac{1}{4}$, $\frac{3}{7}$, $\frac{4}{9}$, $\frac{4}{11}$, but in the Jerusalem artichoke the secondary series $\frac{1}{3}$, $\frac{1}{4}$, $\frac{2}{7}$, $\frac{3}{11}$, $\frac{5}{18}$, occurs frequently, and arises from the breaking up of "tricussate" whorls in an exactly similar manner to the primary series, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{5}$, &c., arising out of opposite leaves. On the other hand spirals do not easily, if ever, return to whorls. If any one will notice how curiously the above is executed in the Jerusalem artichoke, he will see that there is evidently some power at work in the plant which, as it were, compels the spiral to form, and to form mathematically, will be convinced, I am sure, that a "twist" is very far from being the cause—there being none whatever in the cases mentioned above: and further, when whorls break up, the leaves are at first quite irregular, but they gradually "right themselves," acquire the proper angular divergence, and then form some member of the spiral arrangements to perfection.

GEORGE HENSLOW

Flight of Projectiles

IN reply to the letter of "W. Hope," in NATURE of March 13, I request permission to state that by a *simple* formula, I meant one that would be easily understood. I did not intend the word simple to be taken strictly in its mathematical sense.

It is easy for Mr. Hope to employ symbols to represent the initial velocity, angle of elevation, or any other additional particular he may consider necessary for the solution of my problem.

No one possessing the most elementary knowledge of the theory of projectiles can be ignorant of the disturbing elements to which your correspondent refers, or of others to which he makes no allusion. But these cannot be accurately estimated, and, therefore, must necessarily be neglected in a theoretical investigation. I do not anticipate that they will be found to vitiate the results of theory to the extent Mr. Hope supposes.

In the practical application of the formula for which I have asked, the numerical values of the general symbols, would be the *mean* of carefully conducted experiments. Thus the trifling variations arising from slight differences in the charge, the amount of fouling, or other causes, would be reduced to a minimum. The variations in the force and direction of the wind would often neutralise each other. For these reasons I cannot agree with Mr. Hope in thinking that the calculation would be either "useless or deluding," on the contrary I believe it would be valuable as indicating a mean deflection, about which the experimental deflections would be found to group themselves.

Of one thing I am certain, that it would enable us to bring home to the soldier the great effect of wind in deflecting the bullet, and perhaps it might assist us in dispelling the notion of absurdity which is inseparably associated in his mind with the effort to hit something by aiming at nothing. In accomplishing this one of the greatest obstacles to the development of skill in rifle-shooting would be removed.

If Mr. Hope will kindly supply me with the formula which I have asked for, I can assure him that however lightly he may appreciate the results of his labours, by me, at least, they will be valued, and, I venture to hope, made practically useful. Surely he cannot be in earnest in denouncing all theory which approximates to, but does not exactly accord with practice, as "bastard science, or pedantry." If this *dictum* be sound, I can only say it would be easy to show that a great deal of the science of our day, gunnery science in particular, is spurious.

General Didion, a high authority, did not consider my problem unworthy of investigation. In the *Cours Elementaire De Balistique*, he has given a solution which I regret is rather too complicated for my purpose. I should imagine that he would be the last person to expect his theory to afford more than a rough approximation to the results of practice. Hence I conclude that in publishing his calculation for the benefit of the French army, he could have had no conception that his science was "bastard science, or pedantry," and must have been unconscious what a "mischievous unpractical pedant" he was.

Deep Sea Soundings near the Equator

THE following extract from a letter of the captain of the school-ship *Mercury*, occupied at present in taking deep-sea soundings under the orders of the Board of Commissioners of Public Charities and Correction of New York, has been sent to me by General Bowen, of that Board, who takes much interest in the subject. It will doubtless be gratifying to many of your readers:—

"Our Casella-Miller deep-sea thermometer worked admirably. This beautiful instrument stood the test at a depth of 2,040 fathoms, two miles north of the Equator, in longitude 22° 16′ W., when it indicated a temperature of 35° F.; at 1,000 fathoms 38°; at 400 fathoms 41°; at 300 fathoms 44°; at the surface 81°; in the air 80°.

"On our track from the Canary Islands to Rio we found the temperatures at uniform depths to vary about 2°. Our specimens of the bottom from the volcanic region differ in every respect from those obtained in other parts of the ocean."

JOHN WM. DRAPER

University, New York, March 6

SURVIVAL OF THE FITTEST

THE doctrine of the "survival of the fittest" must be strangely understood in some quarters. The American papers report Prof. Agassiz as having expressed himself in this wise at a recent meeting of the Massachusetts State Board of Agriculture, of which he is a member:—"I do not know how animals originated; a brilliant imagination that of Darwin; a very necessary faculty in the scientist. The sense I know too well to misquote him. Hasty generalising of observation is Darwin all over. Natural selection is out of generation. Natural necessity, what is it? Do we find that only the strong beget families? *Observe plants at the foot of the White mountains, where are large trees, and so up to the summit, where they are mere shrubs.* The weak may and do survive as well as the strong. Ignorance lies at the base of the discussion."

Probably no one naturalist, however eminent, can be expected to know everything, or even all simple things. Can it be possible that Prof. Agassiz supposes (as his argument seems to require) that the dwarf trees in question grow and survive near the top of the mountain, *notwithstanding* they are not the fittest, rather than *because* they are the fittest, for the conditions? And does he conceive the doctrine of natural selection to be founded upon some idea of an abstract fitness, irrespective of the conditions, and not upon the survival of the fittest under and in consequence of the conditions? Surely the argument brought against the doctrine is a good illustration in its favour, only an extremely simple and elementary one.

We never could quite comprehend why Prof. Agassiz should give himself so heartily and persistently to the work of demolishing the doctrine of the derivation of species, in all its forms, considering how large and honourable a part he has himself taken in laying the foundation upon which the modern doctrine has been built. Of these foundations none is stronger than the capital one, generally supposed to be established by him, that the succession of species in time corresponds mainly with that in systematic rank, and is also somehow paralleled in the development of each individual of the higher ranks. So that, in view of his continued but unsuccessful efforts to drive the incoming doctrine out of the land, we could imagine him addressing his own important discoveries in the words used by Balak to Balaam:—"What hast thou done unto me? I took thee to curse mine enemies, and behold, thou hast blessed them altogether."

SUB-WEALDEN EXPLORATION.—SECOND QUARTERLY REPORT

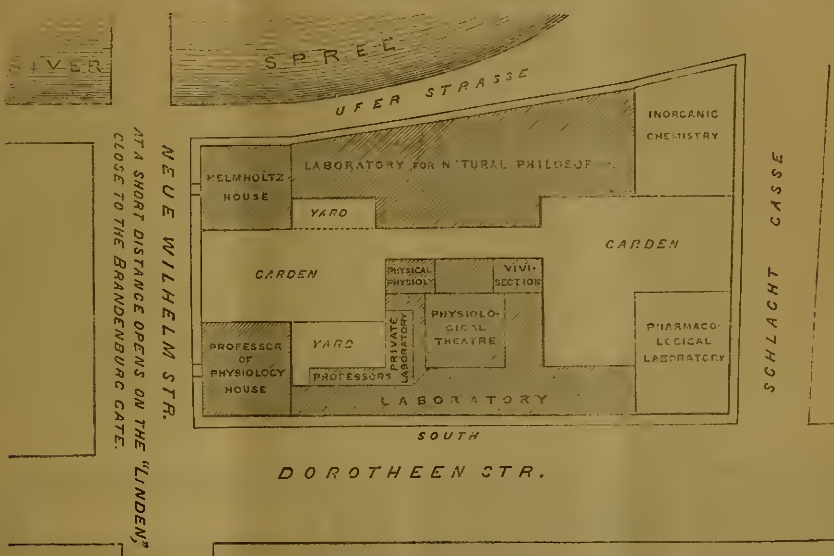
A FRESH survey of the Lower Wealden beds in eastern Sussex by the officers of the Geological Survey Department has quite recently been made. The whole dis-

trict has been recently visited by Messrs. Bristow, Topley, and Drew, and it has been decided to sub-divide the strata hitherto known as the Ashburnham beds into two divisions.

The upper portion, consisting of the mottled clays and shales, will henceforth be called the Fairlight beds, while the lower portion, consisting of shelly limestone intermixed with calcareous shale and *gypsum*, will retain their old title; unless (as is confidently anticipated) they will be found to represent the Purbeck strata, in which case they will be known as the Sussex Purbecks. In reference to our own immediate object, this recent survey has established beyond doubt that the site of the boring is by far the best that the county of Sussex presents for the purpose.

Quite unexpectedly, on January 28, at a depth of 131 feet, a stratified mass of pure white crystalline gypsum (statuary alabaster) was reached. This proved to be over 4 feet in thickness; it was succeeded by 10 feet of gypseous marl; then by 3 feet more of alabaster. Afterwards, we passed through 15 feet of gypsum (more or less impure) varied by seams of crystals of selenite. This discovery has been most opportune. No such accumulation of gypsum was ever met with in Sussex before; and it is some consolation to know that our labour has not been all labour in vain: gypsum is a material which is commercially valuable.

Geologists may therefore inquire, "Where are we now?" The reply is given with caution, and under correction (as the shale seems singularly free from fossils), but as blocks of gypsum are found in the lower strata of the Purbeck series, we assume we are near the base of that formation, and may with some reasonable confidence expect to be able to announce before another quarter is over that we are through these problematical beds, and into the Portland series or some subjacent formation.



Plan of Physiological Laboratories, Berlin

The question of Finance begins to excite some anxiety in the mind of the treasurer. The amount required for machinery, sheddings, &c., has more than doubled the original estimate. Coals, tools, and labour, are each dear, and likely to remain so. The difficulty of access will greatly add to the original estimate of expenses. A large portion of our promised aid is given on conditions which render it unavailable at present.

If 200*l*. could be raised shortly, it would enable the Finance Committee to authorise the call of the second 1,000*l*.; and till this is done we are approaching insolvency. If each existing subscriber would kindly undertake to bring the matter under the notice of some neighbour or friend, we should not only soon raise all we want at present, but be relieved from anxiety for the ultimate prosecution of the enterprise.

We have nothing to do with the commercial value of our present or future discoveries; this will be freely given to those who can utilise it. We can only ask for aid from those who will "give, hoping for nothing again,' except scientific discovery.

THE NEW PHYSIOLOGICAL LABORATORIES AT BERLIN *

THE building of the new laboratory will begin on April 1. The plans are almost ready, and a most glorious place it will be, undoubtedly the finest physiological laboratory as well as the largest which was ever dreamt of. Besides the large theatre, and every possible accommodation for the lectures, it will contain rooms for collections, for a library, a smaller class-room, apartments for three assistants, lodgings for the servant and his family, &c. Then, there are five distinct laboratories most scientifically connected; (1) for physiological chemistry; (2) for physical physiology; (3) for vivisections; (4) for

* Extract from a letter communicated to us by Dr. Bence Jones.

microscopical and embryological investigations. To this laboratory is added a complete aquarium, in which it is hoped to be able to keep all sorts of marine and fresh-water creatures. (5) The private laboratory is organised so as to afford opportunities for every kind of physiological inquiry, so that future professors will feel at home in it, whatever may be their peculiar branch of physiological research. Then, of course, there are dark

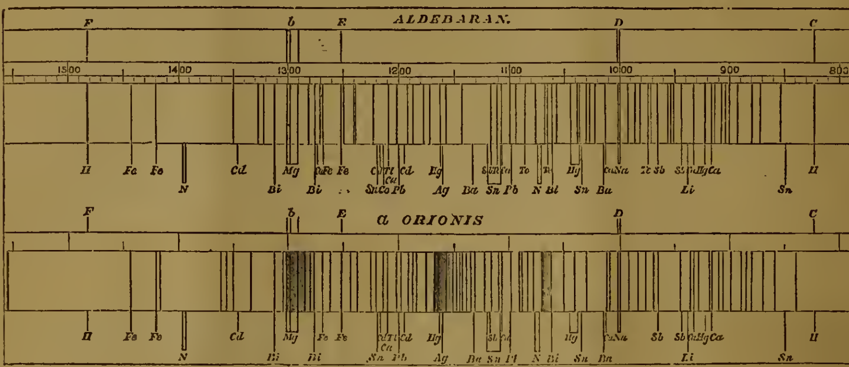


FIG. 34.—Spectra of Aldebaran and α Orionis. (Huggins and Miller.)

chambers looking to the south for optical experiments, rooms for a respiration apparatus, and all sorts of stables, an aviary, a ranarium for the summer, and one for the winter, &c. There is to be a dwelling-house close by, in fact so connected with the laboratory that from the study a lobby and a flight of stairs lead to the private laboratory. The House has been designed entirely according to the English fashion, and wonderful to say, hitherto has not yet met with serious opposition from the architects and the authorities. On the same premises there will be (1) Helmholtz's laboratory and dwelling-house; (2) a laboratory for inorganic chemistry; (3) one for pharmacology, under Leibreich. The accompanying sketch will give an idea of the whole. It covers an area of 4½ acres. The style of building is to be magnificent, much more so than

FIG. 35. FIG. 36.
Fig 35.—Ring Nebula in Lyra, with its spectrum. Fig. 36.—Planetary Nebula in Aquarius, with its spectrum.

is desirable, because the costliness of the establishment increases the responsibility; but now that they are at it, they do not care for ever so many hundred thousands of dollars. All around the buildings, there will be an area, after the English plan, in order to mitigate the tremor occasioned by vehicles. In the Neue Wilhelmstrasse and the hitherto very nasty lane called Schlachtgasse there remains an open space facing the streets, so that the gardens intervening between the two great masses of building get as much light and air as is possible in the town. After all we are not so exclusively military as it may seem at a distance, and some of the French millions find their way into a scientific channel.

ON THE SPECTROSCOPE AND ITS APPLICATIONS

VI.

IN the first place, then, what does the spectroscope tell us with regard to the radiation from the sun and the stars? And here I ask you to neglect and banish from your minds for a time any idea of those dark lines in the solar spectrum that I drew your attention to on a former occasion. I hope I shall be able to explain them satisfactorily to you afterwards, but for the present I wish you merely to take the fact that our sun, but for the dark lines, would give us a continuous spectrum. The spectrum of the stars is very much like the spectrum of the sun. In Fig. 34 is seen a representation of the spectra of two stars, α Orionis and Aldebaran, mapped with the minutest care by Dr. Miller and Mr. Huggins.

FIG. 37.—Spectrum of the Nebulæ.—1, 2, 3, lines observed. Above, the solar spectrum is shown from *b* to F; below, the bright lines of magnesium, nitrogen, barium, and hydrogen, in the corresponding part of the spectrum.

In both cases we should have a continuous spectrum but for the presence of the dark lines. I think you will see in a moment what I am driving at. Suppose the sun or stars composed of only sodium vapour, for instance, it is clear that their light analysed by the prism would give us no great indication of a continuous spectrum, we should merely get one bright line in the orange. But neglect the dark lines for a moment: dealing merely with the continuous spectrum of the sun and star, it shows that we have a something, whether it be solid or liquid, or whether it be a dense gas or a vapour, competent to give us a continuous spectrum. So we are justified in assuming that sunlight and starlight proceed from the incandescence of

a solid, a liquid or a dense gas or vapour. Again, suppose that instead of looking at the sun or the stars we observe the moon, as Fraünhofer did, as has been before stated, what will happen? We get a second edition of sunlight, in exactly the same way as we should get a second edition of the sunlight in the case of a reflection of it from a mirror; and therefore, if proof of such a thing were needed, the spectroscope is perfectly competent to show us that the moon gives us sunlight second-hand. The same in the main with Jupiter, Venus, Mars, and the other planets. If we study them and observe the dark lines we find that the lines which we observe are generally the same as those which we find in the spectrum of the sun. There are other points to which I shall have to draw your attention on a future occasion, but on the whole, the teaching of the spectroscope is, that all those planets are lit up by sunlight as we know them to be.

But we have not yet exhausted the wonders of the celestial field; we have dealt merely with the sun and moon, the stars and planets. What about the nebulæ, those strange weird things, dimly shining in the depths of space, both to the eye and in the telescope obviously

General view. Head and envelopes

FIG. 38.—Views of Donati's Comet.

and distinctly different from anything in the shape of the sun or stars? The appearance of these peculiar bodies is sufficient to show us that we have here something very different from the sun or moon. What is it? You all know as well as I do that ever since nebulæ were discovered mankind have wondered at them, and wanted to know what they were; and you are also aware that it was not settled and could not be settled before the advent of the spectroscope, but that it could be settled in five minutes after that event. Mr. Huggins, who first observed the spectrum of a nebula, found that, instead of the continuous spectrum with which you are familiar in the case of the sun and the stars—always asking you to neglect the Fraünhofer lines, which I shall explain afterwards—the light which he got from the nebula consisted merely of three lines. He was exceedingly astonished, so much so that he thought the instrument might be out of order. However, it became perfectly clear to him in a very short time that there was no mistake at all, and that all that the light which came from the nebula could do was to give him these three faint lines. No doubt you have anticipated my explanation. The nebulæ are composed of tenuous gases or vapours. After what I have said about the way in which the spectroscope at once picks out the difference between a solid or liquid, and a vaporous or a gaseous body, you will see at once that these three bright lines indicate that the nebulæ, instead of being composed of solid, liquid, or densely gaseous bodies—instead of being like the sun or stars—are really composed of rare gases or vapours. Mr. Huggins was enabled, in fact, to determine the gas in one instance, for one of the lines he found was coincident with one of the principal lines in the spectrum of hydrogen one of the other lines possibly being due to nitrogen. And now comes another extremely important point, showing the importance of studying the most minute changes in gaseous spectra, for Mr. Huggins, who knew the spectrum of hydrogen and the spectrum of nitrogen well, and who knew how extremely complicated those spectra are at times, was much astonished at finding only one line of hydrogen and one of nitrogen, and attempted to account for the singleness of the lines, first, by assuming a condition of the gas different from anything

FIG. 39.—1, Spectrum of Brorsen's Comet; 2, Spectrum of Winnecke's Comet; 3, Spectrum of Carbon in olefiant gas; 4, Spectrum of Carbon in olive oil. (Huggins.)

we meet with in our laboratories, and again by assuming an absorbing medium in space. But after Dr. Frankland and myself had made some observations on the spectra of hydrogen and nitrogen, we found it was perfectly easy to obtain, and sometimes when one did not want it, a spectrum of hydrogen or of nitrogen giving only one line, or nearly so; so that by comparing the conditions which were necessary to obtain these conditions in our tubes with the conditions of the nebulæ, it was quite possible to make at all events a rough guess at what is the constitution of the nebulæ, so far as pressure or molecular separation goes. We find, for instance, this single line of hydrogen, and a nearly single line of nitrogen, when the pressure is so slight that you would say that the tube really contained nothing at all, and when, moreover, the temperature is comparatively low. Now, not only is this a fact, which we are quite prepared to assert, merely on the evidence rendered us by these tubes, but I think you will acknowledge that it is entirely in accordance with everything we know astronomically on this subject.

For the next application of the spectroscope in this direction, let us take a comet. The appearance of a

comet is probably well known to many, who will recollect the form of Donati's comet. Although, as you know, that comet appeared only about ten years ago, unfortunately it came too early for us to learn anything about it by means of the spectroscope. We have, first of all, an extremely bright nucleus; then a kind of semilune of greater brilliancy than the rest of the head, then what is called the coma, and the tail. The question which the spectroscope had to put to the comet was—of what is the nucleus composed, and of what is the tail composed. Prof. Donati, and Mr. Huggins especially, to whom we owe so much for his work in this direction, has made some observations on two small comets—I am sorry they were not larger—with considerable success. He found that in the comets he examined, the head gave out a light which very strongly indeed resembled the spectrum of carbon vapour. The spectrum of carbon taken with the spark in olive oil and in olefiant gas differs slightly; the spectrum as obtained from the latter consists of three bands or waves of light, which commence tolerably bright and sharply on the red side, and become gradually fainter towards the more refrangible side. These bands are severally situated in the beginning of the green, in the true green, and in the blue portions of the spectrum. Mr. Huggins has also observed the spectrum of Encke's comet, and has confirmed the result that he previously obtained, viz., that the spectrum of the comet is identical with the spectrum of carbon, as taken in a hydrocarbon. I should like to draw your attention, if there were time, to the way in which these spectra of the carbon spark taken in oil and in olefiant gas, differ.

I have not yet completed all I have to say on the subject of radiation. If, as we have already seen, we take a tube containing incandescent hydrogen and pass a series of intense electric sparks through it, we see that it gives out a red light, which may remind you of some other specimens of radiation which is supplied us by the skies. I allude to the red prominences which are seen around the sun, not in ordinary times, but when the sun is eclipsed. This representation gives you a good idea of what really is seen when the sun is eclipsed, when we have as it were a black sun instead of a bright one, which is really nothing, but the body of the moon. Around this we have a ring of light, which is called the corona, and here and there in this corona we have what are called red flames and red prominences. These red prominences have also on closer observation been found to be only local aggregations or heapings up of a red layer which surrounds the outer edge of the sun. Here, then, it was quite possible that if the newly invented spectroscope were set to question these things, we should see at once whether they were solid or liquid, or whether they were gaseous or vaporous. If we got a continuous spectrum from these red things, we should know that they were solid, or liquid, or densely gaseous. If, on the contrary, we got a bright line spectrum we should know we were dealing with a gas or vapour. You also see that, as the light is red, the chances were that they were not solid or liquid, and then you further see that if the things do consist of a light which does give us lines, a determination of the exact position of the lines, and a comparison of these positions with those of hydrogen, sodium, magnesium, barium, or anything else, would teach us what these things were.

J. NORMAN LOCKYER

PROF. FLOWER'S HUNTERIAN LECTURES

LECTURES XIII. XIV. XV.

TAPIRIDÆ. The geographical distribution of the existing members of this small order is very peculiar, they being confined to the Malay Peninsula, Sumatra, and most of South America. Luna has found their remains in the Post-pleistocene caves of Brazil; they have also been obtained in abundance from similar deposits in North America, and these can hardly be distinguished from those at present existing; in China likewise Pleistocene Tapir's teeth have been found. In Europe during the same time they do not seem to have existed, although Elephants and Rhinoceroses were abundant. In the Pliocene and Miocene, Tapirs are not unfrequently met with at Eppelsheim, Auvergne, and elsewhere; perhaps they originated in Europe, and thence spread east into Asia, and on to America. Respecting their anatomical peculiarities, the teeth are forty-two in number, the anterior lower premolar being absent; the molars and premolars are much alike, forming a uniform series; the incisors are smaller than the canines, they have a small cingulum. The molars are a modification of those of Lophiodon, the transverse ridges are very prominent, and the cusp of the cingulum is less developed. The lower possess two simple transverse ridges, as in Lophiodon, but the last in the series wants the extra back lobe. The anterior nares are very open and the orbit is incomplete behind. There are four toes on the front foot, and three behind; the radius and ulna as well as the tibia and fibia are quite separate and well developed; *T. bairdi* is peculiar in that the mesethmoid cartilage is well ossified, and the maxillaries are specially developed upwards to support it.

The *Palæotheridæ* occur in the Upper Eocene only, they were first found at Montmartre and worked out by Cuvier; since that time they have been obtained from many parts of France, the Bembridge clay, near Yarmouth, in the Isle of Wight, and in Hampshire. Several genera have been separated off, and about a dozen species, from the size of a small rhinoceros downwards. In general aspect they must have been tapir-like. The maxilla curved downwards in front as in the tapirs; the orbital and temporal fossæ were also united, and there were large anterior osseous nares; the feet were much like those of the tapir, though they were more specialised in wanting the fifth toe to the manus. The typical forty-four teeth were present; the incisors were more uniform than in the tapirs; the first pre-molar was rather rudimentary, the others formed a uniform series with the molars, which were wider than from before backwards, much pressed together, and with short crowns. They can be shown to have been developed on the type of Lophiodon, the outer wall bulging inwards, opposite the outer cusps, instead of outwards, giving the earliest indication of the lunate type of tooth; the transverse ridges were normal, and the internal cusps were slightly cut off from them, turning backwards as the rudiments of the posterior semilunes. The lower teeth presented a peculiarity here first noticed, each being formed by a double crescent, quite different from those of the tapir. The last lower molar had a third crescent behind as in Lophiodon and the Artiodactylata, but, different from the latter, in the corresponding milk tooth not presenting it. *Palaplotherium* was a smaller and earlier genus described by Owen from Hordle. In the upper jaw the first premolar was missing, and the corresponding lower one soon lost; the others were comparatively simple. The remains are very abundant, the feet were as in Palæotherium. Gervais has given the name *Propalæotherium* to a few teeth of another early form, intermediate between Lophiodon and Palæotherium. *Anchitherium* was an American form closely allied to the strictly European Palæotheridæ.

Rhinocerotidæ are at present found in Africa and South Asia only; they belong to three types, the African two-horned, non-scutellated; the Asiatic two-horned, and the Asiatic single-horned. The extinct members were numerous; four species existed in England. They did not appear before the Miocene epoch; many are found in America, but not above the Pliocene period. The existing genera have peculiarities in their incisor dentition; these teeth are quite absent in the African, and two above as well as below in the Indian species; when they are

present the outer upper and the inner lower are rudimentary. The canines are absent in all; the full complement of molars are present, of similar character, and degenerating at either end; they are formed on the Lophiodon type; the outer wall is very strong and oblique, with the cusps but little developed and the cingulum large behind; the posterior transverse ridge sends forward a process from near its middle, which in one fossil species (*R. tichorhinus*) is met by another from the anterior wall to form a circular foramen behind the anterior fossa. The lower molars agree with those of Palæotherium, being formed of a double crescent, in which the posterior cornu of the front lunule is partially overlapped by the anterior cornu of the hind one; no third crescent is found on the last molar; three toes are present on all the limbs. They have not been found fossil in the Eocene strata, consequently the American species are among the earliest. Leidy has named an allied genus of small size *Hyracodon*. Its teeth resembled rhinoceros, but the anterior premolars were retained; the peculiar *uncus* on the posterior transverse ridge was wanting, and the proportions of the incisors were reversed. There are several extinct species of the genus Rhinoceros. *Accrotherium* possessed the same number of teeth as the Asiatic genera, but the nasal bones were small, slender, and smooth above, so they could scarcely have carried a horn; it is a Miocene form only; a fifth rudimentary toe was present. Except *R. pleuroceros*, which had two laterally-placed tubercles on the nasal bones, all the other species had them median. They may be divided by their incisors, as are the recent genera, some having them rudimentary, others not. All the European specimens had two horns, with or without functional incisors. The English species, which are not peculiar, are from Pliocene and Pleistocene formations; in *R. leptorhinus* the nasal septum was not ossified; in others it was much so, as in *R. tichorhinus*, a species which has been found preserved by ice in the river Vilni, a branch of the Lena, in Siberia; it possessed a hairy coat and the peculiar pit in the molars mentioned above.

From Port St. Julian, in Patagonia, Mr. Darwin first obtained bones of the peculiar genus *Macrauchenia*, which has not been found out of South America, and only in the Pleistocene deposits there. Prof. Huxley has proved the existence of a second smaller species from some fragments out of a copper mine in Bolivia. Owen showed in his, the first description of the animal, that the vertebræ were peculiar, and agreed with those of the Camels in having the vertebral artery threading a bony canal inside the spinal column, instead of through the bases of the transverse processes. It may be remarked that Myrmecophaga exhibits a similar conformation. But these vertebræ in Macrauchenia are further peculiar in having both ends of the centra quite flat instead of their being opisthocœlous, as in the allied forms. M. Bravard, who was killed in the earthquake at Mendoza, left excellent drawings of the skull and other parts of this animal, which Prof. Burmeister has since published. From them we learn that the skull was not unhorselike; the orbital ring was complete; the palate was not fully ossified between the posterior molars (the camels present the same peculiarity, though Artiodactylate); the nasal bones were extremely reduced, so that the anterior nares were directly above the posterior, and the lower jaw had the angle prolonged. Burmeister thinks, and with good reason, that the animal possessed a fair-sized trunk. There were twenty-four dorso-lumbar vertebræ, of which seventeen were dorsal. The radius and ulna, as well as the tibia and fibula, were fused throughout. The femur possessed an extremely small third trochanter; and there were three toes to each limb. The astragalus was strongly Perissodactylate, no cuboid facet being present. Our knowledge of the teeth is somewhat deficient, as they are always preserved in a much worn state. The typical forty-four were present; the incisors were equine, and the canines of the same size; the back molars were the bigger and the anterior premolars comparatively simple. The lower molars formed double crescents, as in Palæotherium.

In tracing back the descent of the *Equidæ*, the Palæotherium d'Orleans of Cuvier has been shown to be generically different, and has been called *Anchitherium*; it is also found in Nebraska. These were small horse-like animals with teeth much as in Palæotherium, forty-four in number; the first premolars were very small, and no pit was present in the incisors; the outer wall of each molar was also concave opposite the cusps; the lower molars formed double crescents, and the last possessed the extra lobe. The ulna and fibula were fused with the radius and tibia respectively; the astragalus had some of the obliqueness of that of the horse, which it resembled in many other points. But there were three toes on the limbs, the lateral ones being less strong than the median. A peculiar antorbital fossa was present.

The horse must be described before the affinities of its close allies can be realised. In it the incisors possess the well-known pit; the canines are rudimentary in the mare; the premolars resemble the molars, and the crowns are very long and deeply embedded, with a concave crescent opposite the tubercles on the outer wall and the anterior internal tubercle insulated at first; otherwise they are typical. The depressions are very deep and are filled up by cementum, to form a solid mass. The lower molars are slightly complicated double crescents. The ulna and fibula are not free. *Hipparion* had very horse-like teeth. It is a later Miocene form, and is common in the New and Old World. It possessed the antorbital pit, as in Anchitherium, but was otherwise very equine. The canines were present in both sexes of equal size, and the anterior internal tubercle of the molars was completely insulated. The median of the three digits alone was functional. *Merychippus*, a Pliocene form, recognised by Leidy from some teeth, seems to have been an intermediate form between these and Anchitherium. Fossil true horses abound in America as well as the Old World; they since became extinct in the former locality. They are found in the Pleistocene nearly everywhere; their earliest remains are from the Sevalik Hills.

With these animals the description of the fossil Perissodactylata terminates.

PERCEPTION IN THE LOWER ANIMALS

LETTERS on this interesting subject still continue to pour in upon us in so great abundance that limited space compels us to select merely the facts contained in each. The best service we can at present render to the unravelling of the, we think, yet unsolved problem is simply to accumulate facts; no doubt a satisfactory explanation will by-and-by be arrived at. First we must give place to Prof. Croom Robertson, who thus writes as to the theory broached in his former letter:—

In my former letter I made no pretension to explain all the wonderful feats reported of dogs or other animals, but only argued, in the wake of Mr. Wallace, that it had never been sufficiently considered what help in finding their way dogs might have from smell alone. Be the help what it may in the particular cases, I thought it clear that, if in their common experience smell does not somehow supply to dogs the defect of touch, they are, as far as we can see, badly fitted out, by comparison with men, for making their way through the world. And, even after your article of last week, I must still in their interest hope that the notion of a continuous world of smells is not an impossible one.

If the external world were the same to dogs that it is to men—a complex of interwoven touches and sights in space, and only in addition dogs had more frequent and varied experiences of smell, the dying away or shifting of some in a particular train of odours would doubtless, as the writer of the article urges, put a dog out

when reduced to work its way back along such a train. But my point is, that a dog will regularly think of all things, stationary or moving, by their smell, where we think of them by their touch as handled, and this upon the simple ground of fact that a dog has no hands; in which case the continuity of a road will as little to the dog as to us depend upon the standing-still of flocks of sheep or any other passing objects. It is true that our experience does not enable us easily to fancy what sort of world this of the dog's will be, but at the worst we need not conceive it, with the writer, upon the analogy of a succession of coloured mists. Do we, even with our intermittent smell, find it so impossible to refer the diffused odour of a dung-hill to a particular source? Or, to take a fair parallel case, if a sound is diffused so that it may be heard anywhere throughout a great hall, do we therefore suppose it to be everywhere and not to emerge from a definite spot? To the psychologist the strictly tactile properties of objects are themselves but sensations, which we are determined to project away from us in a certain definite order—as it happens, a very sharply defined order. With different means of projection and different sensations to project, how should the dog not have its own different world—the best it can devise out of its experiences?

Such reference to the fact of a dog's organs of sense being what they obviously are, ought not to be discounted as mere speculation, but perhaps that must be borne with. Facts of the other sort—reports, more or less authentic, of the feats of particular dogs—when made a ground for ascribing to the species preternatural powers of divination, merely because the facts are not explicable under the conditions of human experience, are beset with their own difficulty. Dogs do not always find their way back, even from the next street. Let all that side of the matter be thought of, before we suppose some unerring instinct to account for the remarkable enough feats of some that cannot be denied. Of course no train of evanescent smells can guide a dog back upon a road from which they have died away; as little, or still less, can the succession of particular smells, however constant, lead a dog right upon a line that he has never travelled over before. But that dogs, while they have no such touch as ours, do constantly use their sense of smell to guide them, cannot be doubted; and the result to them must be such a very different world of experience from ours, though developed under common laws of acquisition, that we have no means of deciding what it is impossible to be done by *some* dogs through mere experience.

One of your correspondents, Mr. Brewer, had good remarks in this sense the other week. One point he raised besides upon which I would add a word. The point was whether for the dog smells would enter, instead of touches, into that fundamental experience of an external world, of which visual sensations are but marks or symbols. I should imagine that they would enter into its experience of modes of extension, by us acquired chiefly through the moving hand. But into the experience of modes of resistance, the general tactile sensibility diffused over the surface of the body would enter for the dog as well as for us.

Mr. George Henry Lewes appends to his letter on p. 401 of this week's NATURE, the following contribution to this subject:—

Gratiolet, in his work on the "Nervous System," mentions that a dog of his was always thrown into convulsions of terror by the scent of a small piece of wolf's skin, which was so old that it was worn to a shred. In my room there is a perfectly unworn wolf skin made into a rug, and on this my bulldog was accustomed luxuriously to stretch himself, without any but pleasurable emotions. Now this may have been due either to his imperfect sense of smell or, what is more probable, to his not having inherited any terror from ancestors more likely to attack than to be afraid of a wolf.

Mr. Laughton, of the Royal Naval College, Greenwich, sends us a valuable letter, from which we extract the following:—

A passage in Sir Bartle Frere's paper on Cutch (Journal of the Royal Geographical Society, vol. xl. p. 186), seems to bear on this subject which has been interesting the readers of NATURE for some weeks past. He says:—"As elsewhere in the plain country of Sind, and here more conspicuously, owing to the absence of any prominent natural features or marked tracts, the best guides seem to depend entirely on a kind of instinct—they will generally indicate the exact bearing of a distant point which is not in sight quite as accurately as a common compass would give it to one who knew the true bearing. They affect no mysterious knowledge, but are generally quite unable to give any reason for their conclusion, which seems the result of an instinct—like that of dogs and horses and other animals—unerring, but not founded on any process of reasoning, which others can trace or follow."

I incline strongly to the solution put forward by the writer in the *Quarterly* (see letter in last number). If to this we add the consideration that dogs certainly can and do interchange ideas, and may therefore question other dogs as to the general direction in which they wish to go, the two together seem to offer a reasonable though hypothetical explanation of the very curious facts referred to.

Mr. George R. Jebb, of Shrublands, Chester, writing on March 18, says—

Last Thursday I sent my terrier dog (Tartar) by train from Chester to Shrewsbury by Great Western Railway (*i.e.* by way of Wrexham and Ruabon), I myself went by the North Western line *via* Broxton and Whitchurch; the distance by the former road is 42 miles, by the latter 38: the two railways diverge from each other for some 20 miles from Chester, and are then 16 miles apart; they afterwards converge and join at Shrewsbury. Tartar was sent from Shrewsbury to Broxton station, which is 10 miles from Chester, by the 2.55 train. I had previously arranged with the station-master to keep the dog for five or ten minutes after the departure of the train, and then to set him at liberty on the public road. The train arrived at Broxton at four o'clock. Tartar hung about the station till nearly 5.30, perhaps longer, as he was not seen starting off. He was at home at Chester at nine; he was not at all distressed. It is probable, I think, that he came back pretty direct. It is certain he came across ten miles of country, the greatest part of which he had never traversed before. It is also certain he did not return *via* Shrewsbury, as there was not time. He had never been at Broxton before.

Does not this experiment seem to prove that dogs—some at least—possess the wonderful power (the nature of which is at present unknown) of arriving at the knowledge of the *direction* of their home when they have been taken from it long distances by circuitous routes? And if so, is it not more probable that a dog when lost usually makes use of this power to guide himself home by the shortest practicable road, than that he finds his way back "by means of the odours he took note of" on the outward journey? How do pigeons find their way home? A railway contractor told me he has a pony which he uses chiefly for drawing a light "lorry" upon a tramway now in course of construction. There are on this tramway some loops or passing places for waggons at intervals of a mile or so. These points are dangerous if passed too quickly. The contractor drives the pony himself often at a very fast rate. The pony will on the darkest nights suddenly pull up at the dangerous points without the slightest check from the driver, who otherwise would be obliged to proceed with the greatest caution. Does the pony know his whereabouts by the sense of smell, hearing, or touch? Probably, I should say, by all three acting in unison.

The Rev. O. Fisher, of Harlton, writes:—

On a bright day when I have flowers in my window, bees frequently precipitate themselves against the window-panes, evidently desirous of reaching the plants. This is easily explained by the sense of sight; but the remarkable thing is that they do the same when the blind is drawn down, so that they cannot see the flowers, and it seems impossible that they should smell them while the window is shut. Can it be that that all-pervading æther, which brings light to our eyes, and is also believed to convey the magnetic and electric forces through media impervious to light, may act in a manner other than luminiferous towards some animals, and produce "action at a distance" upon their organs?

A Scotch correspondent, R. C., who has given us his full name and address, sends us the following interesting facts:—

A few years ago a sheep, one of a flock, belonging to Mr. Miller, flesher, Beith, Ayrshire, gave birth to three lambs; thinking that three were too heavy for the mother to suckle, he gave one to a farmer, who lived three quarters of a mile from the field where the sheep lambed. This one was taken away from the mother when barely a day old, and carried to the farmer's, where it was shut up in a close house.—

Two days after it found its way out, the door having been left open, and immediately made off for the field from which it had been taken. The writer met it near the field walking (it having chosen rightly between two branches into which the road diverges between the field and the farm-house) on the grass on the side of the road: the farmer, an old man, was in pursuit, and called upon the writer to turn it back, which he did, but not without some difficulty, as it crossed from side to side, and made efforts to pass on, with all the tactics of an old animal, while it was barely three days old, and had been barely one when it was brought from the field.—I have the following from a well-authenticated source. A farmer in Bogside, Beith, of the name of Fleming, was looking out of his window one summer's morning, about three o'clock, when he saw a fox crossing a field before it, carrying a large duck that he had captured. On coming to a stone dyke about four feet high, on the side of the field, Reynard made an effort to leap over it with his prey, but failed, and fell back into the field. After making three attempts with the same result, he sat down and viewed the dyke for a few minutes; after apparently satisfying himself, he caught the duck by the head, and standing up against the dyke with his fore paws, as high as he could reach, he placed the bill of the duck in a crevice in the wall; then springing upon the top, he reached down, and pulling up the duck dropped it upon the other side, leaped down, and picking it up, went on his way. If this is not reason, it is nearly akin to it.

We conclude with the following instances sent us by Mr. G. J. Romanes, of Cornwall Terrace, Regent's Park:—

A Colley dog accompanied his master with a flock of sheep down the Caledonian Canal, and between Oban and Greenock suffered much from sea-sickness. Several months afterwards a similar journey was undertaken by the same dog and man with another flock of sheep. Upon quitting the wharf at Oban, the dog, remembering that this was the point at which his troubles began on the former occasion, jumped ashore, leaving his master with the sheep on board the steamer. Upon landing at Greenock the man was surprised to find his dog upon the quay awaiting his arrival—the animal having run by land from one wharf to the other, over ground which he had never before traversed. The distance between Oban and Greenock is fifty miles in a straight line, but as this passes over high mountains as well as through a lake and two arms of the sea, it is not likely to have been the route taken.

My authority for this account is a leading clergyman in Glasgow, who would, no doubt, be willing to give his name to any one desiring it.

The second instance, in its bearing upon Mr. Wallace's theory, is even more conclusive. Another dog of the same kind sailed with his master from Wick to Berwick, where he was lost. Ten (?) days afterwards he appeared at his home in Sutherlandshire, footsore and exhausted, having, it must seem, run nearly the entire length of Scotland. I am indebted for this information to a medical army-officer and well-known C. B. who had heard it from the owner of the dog. As my friend is at present in ill-health, I am unable to refresh my memory as to the number of days occupied by the dog's return journey, but I think it is correctly stated.

NOTES

THE meeting to which we alluded last week in connection with a memorial to the late Prof. Sedgwick, was held on Tuesday, and was attended by a large number of scientific and university friends of the late eminent geologist. Resolutions were passed that a geological museum be erected, to be called the Sedgwick Museum, and that a bust of the professor should be placed in it. A Cambridge and a London Committee were appointed. The Prince of Wales wrote that the object of the meeting would have his warm support, from the feeling of respect he entertained for the late professor.

SOME efforts are now being made gradually to give the same stimulus to the higher education of women as of men. The National Union for Improving the Education of Women has offered seven scholarships of 25*l.* each, tenable for one year, for competition throughout the United Kingdom, the competitors to be young women over sixteen years of age. The scholarships will be awarded at the local examinations held during the present year by the Universities of Oxford, Cambridge, and Edinburgh, and Trinity College, Dublin, the Science and Art Department, the Society of Arts, and the College of Preceptors.

THE examiners for the Cambridge Natural Sciences Tripos for 1872 have represented to the Board of Natural Science Studies that they are of opinion that the time has now come when an increase in the number of examiners is urgently required. The amount of physics now included in the subjects of examination is so large as to make it impossible to treat the examination in this subject any longer as an appendage to the examination in chemistry. The subjects of comparative anatomy, zoology, and physiology are also too wide to be undertaken as a general rule by one examiner. An increase in the number of examiners to seven would make it much more often possible to secure a real examination of the answers by two examiners, which is unquestionably desirable. The Board therefore recommend that in Regulation 10 for the Natural Sciences Tripos, for the words "two examiners" the words "three examiners" be substituted, and for the words "third examiner" the words "fourth examiner" be substituted, and for the words "five examiners" the words "seven examiners" be substituted. They recommend further that, in order to ensure the regular rotation of examiners, five examiners be nominated by the Board in the present year, of whom one shall be nominated to hold office for one year only.

MR. ARTHUR MILMAN, son of the late Dean of St. Paul's, has been appointed Assistant-Registrar to the University of London, in the room of Dr. Hirst.

IT is understood that Mr. Fowler, of Lincoln College, Oxford, author of the two works on Deductive and Inductive Logic, will be a candidate for the Professorship of Logic, vacant by the recent death of Prof. Wall. The appointment is made by Convocation.

THE late Mr. Julius Brenchley, whose death a month ago has been a great loss to scientific collectors, as well as to the town of Maidstone, left as the results of his voyage in the South Pacific, the last of his most extensive travels, the manuscript together with the plates which illustrate it already drawn, of a work which he fully intended to have had printed, on the natural history of those regions. It is to be hoped that some means will be taken to insure their publication.

IT is satisfactory to find that the new "Spanish Society of Natural History" is continuing its career undisturbed by the political troubles around it. The third part of its Annals bearing date March 5, 1873, has reached this country, and is quite up to the mark of the parts which have preceded it. It contains the conclusion of Vilanova's paper on "the Pre-historic in Spain;" a catalogue, by Gundlach, of the mamifera of Cuba; a paper by Sharp, describing a new species of Spanish Coleoptera, and containing the descriptions of several new blind beetles from the caves of the mountains of the Asturias; a paper, by Colmeiro, on the elevations attained by cultivated plants in Ecuador; also a long and careful paper by Colmeiro, on the Legum nosæ of Spain and Portugal. This part completes the first volume, and contains index, and list of the members of the Society. On inspecting the latter it appears that only two of our countrymen have joined the Society. This fact has, we believe, been a considerable disappointment to the founders of the Society, who hoped it would meet with a liberal support in this country. We hope that when the existence of the Society and the merit of its publications become more widely known, it will receive the recognition it deserves.

The brothers Godeffroy, large merchants of Hamburg, through the instrumentality of several collectors in the Pacific Islands, have accumulated a large number of specimens of marine and other animals, many of great rarity. They have lately placed their material in the hands of naturalists who interest themselves in the different departments, and their results are being published in the *Journal des Museum Godeffroy*, a quarto work, the first part of which, excellently illustrated, has just appeared.

Prof. Max Muller delivered his first lecture on Mr. Darwin's Philosophy of Language at the Royal Institution last Saturday; the other two will be given on Saturday next and Saturday week. From the syllabus which is before us, these lectures are likely to be of high value, and to throw much light on the subject under discussion, and in general on the place of man with reference to the lower animals. No doubt the lectures will be given to the world in a more permanent form after their delivery at the Royal Institution.

The Rev. Mr. Moyle, lately sentenced to penal servitude, is not, as stated in the newspapers, a Fellow of the Royal Society.

The Geologists' Association have arranged the following visits for March and April:—Thursday, March 27—Visit to the British Museum, at 3 P.M., to inspect those portions of the Botanical Collection interesting to geologists. Thursday, April 3—Visit to the Museum of the Royal College of Surgeons, at 3 P.M., to inspect the Hunterian and Zoological Collections preserved in the Museum of the College. Easter Monday and Tuesday, April 14 and 15—Excursion to Banbury, Oxfordshire, assembling at the Red Lion Hotel, Banbury at 12.30 P.M. Monday, April 21—Visit to the Museum of Practical Geology, at 8 P.M. under the guidance of Mr. Etheridge, to inspect the Palæontological Collections exhibited in the Galleries of the Museum. Saturday, April 26—Excursion to Charlton from Charing Cross by the 2.52 P.M. North Kent.

The second annual meeting of the Glasgow Society of Field Naturalists was held on the evening of Tuesday the 18th inst., Mr. J. Allan, vice-president, in the chair. The report read by the Secretary showed that a considerable amount of work had been done during the year. Twelve excursions were held to places of interest in the neighbourhood. The papers read were numerous, varied, and interesting, and a large number of specimens were exhibited. The branches to which more particular attention was given were botany, entomology, and marine zoology.

The largest catalogue of stars that has ever been published in America is now about to appear from the United States Naval Observatory at Washington. This work, as we learn from a recent communication of Prof. Yarnall, will embody all the valuable observations made since the foundation of the observatory, in 1842, with the meridian instruments, consisting of the work of the well-known astronomers, Coffin, Hubbard, Ferguson, Newcomb, Hall, Harkness, and Yarnall. Over fifteen years of labour have been devoted to it by Prof. Yarnall and his assistants, and he has himself made nearly one half of the observations. The catalogue will be based on over eighty thousand observations of more than ten thousand stars, many of them being quite faint, and in extreme southern latitudes, such as have never, or rarely, hitherto been observed.

By the publication of a supplementary number, containing the proposed corrections of plates already issued, the important work of Mr. William H. Edwards upon the butterflies of North America, completes its first volume. No American work of the kind has ever been printed containing in its pages so satisfactory illustrations of the various species, new and old, as this of Mr. Edwards. The volume, as finished, embraces fifty plates, each containing several figures, representing all the varieties of each species.

At the annual meeting of the Royal Irish Academy, held on Saturday evening, the 15th inst., the Cunningham Gold Medal was presented to Sir William Robert Wilde, Knt., M.D., in recognition of his valuable services in the compilation of the Museum catalogue, and in the arrangement of the Museum.

The American Palestine Exploration Society has reached Syria, under the command of Lieut. Steever, United States Cavalry, accompanied by Prof. Paine, formerly of Robert College, Constantinople, and by other persons, and at last advices was fitting out at Beyrout, with a view of taking the field early in March. An arrangement has been made with the British Palestine Exploration Society by which the whole country east of the Jordan, and embracing the old territories of Moab, Gilead, and Bashan, are to be relinquished exclusively to the American society, and it is expected that, abounding as it does with ancient ruins and excavations, objects of much interest will be brought to light.

Among other bills lately presented to Congress is one for the establishment of a National Photographic Institute, which provides for the establishment of such an organisation in Philadelphia, where the entire theory and practice of the photographic art are to be taught by competent professors, under the direction of the National Photographic Association of the United States. The bill also provides that the sum of 30,000 dollars shall be appropriated for the purchase of a suitable building and apparatus, but that the institution shall be self-supporting, and only such fees shall be paid by the students as shall meet the actual expenses.

We have received a couple of Salem (Massachusetts) papers, containing detailed accounts of the celebration on March 5 of the 25th anniversary of the Essex Institute of that city. This institute, mainly scientific in its aims, can trace its origin under various forms to about the middle of the last century, and under its present name was constituted by the union in 1848 of the Essex Historical and the Essex County Natural History Societies. Prof. O. C. Marsh, of Yale College, who was present, spoke of the good work which the institution has done in diffusing scientific knowledge and encouraging other societies; he also acknowledged that it was at the hands of this institution that he acquired his first taste for scientific investigation.

Mr. Partridge, for many years Professor of Anatomy to the Royal Academy, died on Tuesday, 25th inst.

The following telegram from Mr. Cowie, Shanghai, dated March 25, 4^{h} 5^{m}, has been received by Mr. J. R. Hind:—"Your predicted circular black spot on sun, seen here distinctly at 9 morning, 24th." This of course refers to the possible transit over the sun's disc of an intra-Mercurial planet, and although it is very unlikely that Mr. Cowie's is a genuine find, the mere fact that he should put himself to the trouble and expense of sending such a telegram all the way from Shanghai, is an encouraging sign of the increasing and wide-spread interest taken in science.

An International Congress is to meet in Vienna on August 4, to discuss the question of Patent Rights. The Congress, which was suggested by President Grant, will consist of scientific men, manufacturers, political economists, and skilled workmen. Each Government will be represented by a special delegate.

The *Practical Magazine* has now reached its third number, and so far has carried out satisfactorily the promise of its prospectus; its main aim being to carry out a careful and systematic survey of the Industrial Activities of America, Germany, and France, in order to present at the earliest possible moment such information as is likely to be useful to British practical men. We believe there was a place in Britain for such a journal, and if the *Practical Magazine* continues as it has begun, we have no doubt it will satisfactorily fill this place. In get-up, paper, printing, illustrations, &c., it is one of the handsomest journals

we have seen, and we hope it will have many readers both among industrial employers and employées.

Two attempts have recently been made from Norway to reach Spitzbergen in the middle of winter, for the purpose of taking additional supplies to the storehouse at Eisfiord, erected and fitted with all necessaries last summer, as we noted some months ago, for the purpose of sheltering the exploring expeditions which are endeavouring to penetrate polewards to the north of Europe. The steamer *Albert* left Tromsoe on November 20, and reached about 77° under the meridian of Greenwich, when, on account of the great danger from the ice, not to mention the unbroken twilight, and the improbability of reaching the goal, it was determined to put back. One result of the voyage is the observation that the temperature of the sea at that season is several degrees higher than that of the air. In spite of the failure of the *Albert*, the sailing-vessel *Isbjärn* left Tromsoe on December 24, with the same object in view, and came within sight of Bear Island on January 7, which, however, it was found impossible to reach. After one or two attempts in other directions, the *Isbjärn* was compelled to put about, more from the difficulty of managing the frozen sails than from the danger from ice and the inconvenience of perpetual darkness. Notwithstanding these two failures, we learn from *Les Mondes* that M. Rosenthal, of Bremen, has fitted out his steamer *Groenland* for another attempt. M. Rosenthal has already lent his vessels to the service of science, and we hope this third attempt may be more successful than the previous ones, though it seems hopeless.

An advanced sheet sent us of Petermann's *Mittheilungen* contains an article on King Karl Land, the island which lies to the east of Spitzbergen. English geographers identify this island with Wiche Land discovered by the Englishman Edge, in 1617, while Prof. Mohn, the writer of the article referred to, claims it for the Norwegian discoveries of 1872, and names it King Karl Land, after King Karl XV., of Norway and Sweden. Dr. Petermann maintains that Wiche Land has no existence, as the position given to it until recently in the maps was considerably south of King Karl Land, where there is nothing but water. Dr. Petermann in a note to us suggests that if the English Admiralty or any private English expedition should explore and survey it thoroughly, there might be no objection to naming it afresh. The naming of any geographical discovery is not of very great importance, but it seems to us that the discovery of the island really belongs to Edge; all that can be said against it is that either he or subsequent geographers misplaced the island by a few degrees. On the same ground the credit of many early discoveries might be taken away from those to whom it is justly attributed.

It is said that an American aëronaut, Prof. Donaldson, intends this summer to cross the Atlantic to Ireland in a large balloon. The machine will weigh about 2,000 lb, will contain 268,000 ft. of gas, with two reservoirs to provide against leakage, and an electrical arrangement for light. The professor calculates to accomplish his trip in from 17 hours to two days and a half, and intends, if the experiment proves successful, to establish a balloon mail and passenger line round the world.

The additions to the Zoological Society's Gardens during the past week included a short-toed eagle (*Circaëtus brachydactylus*), and two Algerian tortoises (*Testudo mauritanica*), from Morocco, presented by Capt. Perry; a white-faced tree-duck, (*Dendrocygna viduata*), and a Capoeira partridge (*Odontophorus dentatus*), from Brazil, and a crocodile from Sumatra, deposited; a Great kangaroo (*Macropus giganteus*), and a vulpine phalanger (*Phalangista vulpina*), born in the gardens; three red-breasted cardinals (*Paroaria cucullata*) from South America, and a western ground parrakeet (*Geopsittacus occidentalis*) from South Australia, purchased. Only one specimen of the last mentioned extremely rare bird has been previously alive in the gardens.

SOCIETIES AND ACADEMIES

London

Royal Society, March 20.—"On the Temperature at which *Bacteria*, *Vibriones*, and their Supposed Germs are killed when immersed in Fluids or exposed to Heat in a Moist State." By H. Charlton Bastian, M.D., F.R.S., Professor of Pathological Anatomy in University College, London.

For more reasons than one, we may, perhaps, now look back with advantage upon the friendly controversy carried on rather more than a century ago between the learned and generous Abbé Spallanzani and our no less distinguished countryman Turberville Needham. Writing concerning his own relation to Needham, the Abbé said*:—"I wish to deserve his esteem whilst combating his opinion;" and, in accordance with this sentiment, we find him treating his adversary's views with great respect, and at the same time repudiating much of the empty and idle criticism in which so many of Needham's contemporaries indulged with regard to his work. This criticism Spallanzani says†:—"Without looking into details, contented itself by throwing doubt upon some of the facts, and by explaining after its own fashion others whose possibility it was willing to admit." He moreover warmly reprobated the ignorant and disrespectful statements made by an anonymous writer who had shown himself little worthy of being heard upon the subjects in dispute. Spallanzani on this occasion very wisely said‡:—"When it is a question concerning observations and experiments, it is necessary to have repeated them with much circumspection before venturing to pronounce that they are doubtful or untrustworthy. He who will allow himself to speak of them with contempt, and who can only attempt to refute them with writings composed by the glimmer derived from a treacherous lamp, will not find himself in a condition to retain the esteem of learned men." The anonymous writer (in his 'Lettres à un Americain"), to whom Spallanzani referred, had gone so far as to doubt the statements of Needham as to the constant appearance of organisms in infusions which had been previously boiled, and also intimated that even if they were to be found, it was only because they had been enabled to resist the destructive influence of the boiling fluid. This latter assertion was emphatically denied by Spallanzani—his denial being based upon a most extensive series of experiments with eggs in great variety and with seeds of all degrees of hardness. These were all found to be killed by a very short contact with boiling water. Spallanzani had thoroughly satisfied himself that even very thick-coated seeds could not resist this destructive agent, whilst he thought that the idea entertained by some, of the eggs of the lowest infusoria being protected from the injurious influence of the boiling water by reason of their extreme minuteness, was a supposition so improbable as scarcely to deserve serious consideration. Such a notion was, he thought, wholly opposed to what was known concerning the transmission of heat. Whilst, therefore, the opinion of those who believe that eggs have the power of resisting the destructive influence of boiling water could be wholly refuted, Spallanzani thought it by no means followed that the infusoria, which always after a very short time appeared in boiling infusions, had arisen independently of the existence of eggs. The infusions being freely exposed to the air, it was very possible that this air had introduced eggs into the fluids, which by their development had given birth to the infusoria.§

After the lapse of a century it has at last been clearly shown that this supposition of aërial contamination advanced by Spallanzani (warrantable and natural as it was at the time) is one which, in the great majority of cases, is devoid of all foundation in fact, so far as concerns the organisms essentially associated with processes of putrefaction, viz., *Bacteria* and *Vibriones*. The means of proving this statement, based upon independent observations made by Prof. Burdon Sanderson and myself, were recently submitted to the consideration of the Royal Society.‖ Before the reading of this communication I was under the im-

* "Nouvelles Recherches sur les Découvertes Microscopiques et la Géoération des Corps Organisés, &c. London and Paris, 1769, vol. i. p. 69.

† *Loc. cit.* p. 9.

‡ *Loc. cit* p. 114.

§ A few pages further on this view is thus shortly expressed.:—"Il est évident que toutes les tentatives faites avec le feu, peuvent bien servir à prouver que les animaux microscopiques ne naissent point des œufs que l'on supposit exister dans les infusions avant qu'on leur fit sentir le feu: mais cela n'empéche, pas qu'ils n'aient pû être formés de ceux qui auront été portes dans les vases après l'ébullition."

‖ See Proceedings of Royal Society, No. 141, 1873, p. 129.

pression that almost every one of those who had taken part in controversies which had been carried on both here and abroad concerning the Origin of Life, were prepared to admit, as Spallanzani had done, that the eggs or germs of such organisms as appear in infusions were unable to survive when the infusions containing them were raised to the temperature at which water boils. This impression was produced in part by the explicit statements on the subject that had been made by very many biologists, and also in part by a comparatively recent and authoritative confirmation which this view as to the destructive effects of boiling infusions upon *Bacteria* had received. Little more than two years ago Prof. Huxley, as president of the British Association for the Advancement of Science, recorded experiments in his Inaugural Address which were obviously based upon this belief as a starting-point. And subsequently, in one of the Sectional Meetings, after referring to some of my experiments, and to the fact that all unmistakeably vital movements ceased after *Bacteria* had been boiled, Prof. Huxley added: *—"I cannot be certain about other persons, but I am of opinion that observers who have supposed they have found *Bacteria* surviving after boiling have made the mistake which I should have done at one time, and, in fact, have confused the Brownian movements with *true living* movements." Prof. Huxley does not now (in reference to the experiments cited in my last communication) suggest that the organisms found in the infusions were dead and had been there before the fluids were boiled: he expresses doubts concerning that which he seems formerly to have regarded as established, and, with much caution, wishes for evidence confirmatory of his own, to show that the germs of *Bacteria* and *Vibriones* are killed in a boiling infusion of hay or turnip, as they have been proved to be in "Pasteur's Solution" and in solutions containing ammonic tartrate and sodic phosphate

With the view of removing this last source of doubt more effectually, and also of refuting the unwarrantable † conclusions of M. Pasteur, to the effect that the germs of *Bacteria* and *Vibriones* are not killed in neutral or slightly alkaline fluids at a temperature of 212° F., I almost immediately after the reading of my last communication commenced a fresh series of experiments.

Nearly two years ago, in my "Modes of Origin of Lowest Organisms," I brought forward evidence to show that *Bacteria*, *Vibriones*, and their supposed germs, are killed at a temperature of 140° F. (60° C.) in neutral or very faintly acid solutions containing ammonic tartrate and sodic phosphate, and also evidence tending to show that these living units were killed in neutral infusions of hay and in acid infusions of turnip at the same temperature.

The crucial evidence adduced concerning the degree of heat destructive to *Bacteria*, *Vibriones*, and their germs, in the saline solution was of this nature. The solution had been shown to be incapable of engendering *Bacteria* and *Vibriones* (under all ordinary conditions) after it had been boiled, although it still continued capable of supporting the life and encouraging the rapid multiplication of any of these organisms which were purposely added to it. Some of this boiled solution, therefore, was introduced into flasks previously washed with boiling water; and when the fluids had sufficiently cooled, that of each flask was inoculated with living *Bacteria* and *Vibriones*—in the proportion of one drop of a fluid quite turbid with these organisms to one fluid ounce of the clear saline solution. ‡ These mixtures containing an abundance of living organisms were then heated to various temperatures, ranging from 122° F. (50° C) to 167° F. (75° C.), and it was invariably found that those which had been heated to 122° or 131° became quite turbid in about two days, whilst those which had been raised to 140° F. or upwards as invariably remained clear and unaltered. The turbidity in the first series having been ascertained to be due to the enormous multiplication of *Bacteria* and *Vibriones*, and it being a well-established fact that such organisms when undoubtedly living always rapidly multiply in these fluids, the conclusion seemed almost inevitable that the organisms and their germs must have been killed in the flasks which were briefly subjected to the temperature of 140° F. How else are we to account for the fact that these fluids remained quite unaltered although living organisms were added to them in the same proportion as they had been to those less-heated fluids which had so rapidly become turbid? Even if there does remain the mere possibility that the organisms and their supposed germs had not actually been killed, they were certainly so far damaged as to be unable to manifest any vital characteristics. The heat had, at all events, deprived them of their powers of growth and multiplication, and these gone, so little of what we are accustomed to call "life" could remain, that practically they might well be considered as dead. And, as I shall subsequently show, the production of this potential death by the temperature of 140° F. enables us to draw just the same conclusions from other experiments, as if such a temperature had produced a demonstrably actual death. Seeing also that these saline solutions were inoculated with a fluid in which *Bacteria* and *Vibriones* were multiplying rapidly, we had a right to infer that they were multiplying in their accustomed manner, "as much by the known method of fission, as by any unknown and assumed method of reproduction." So that, as I at the time said,* "These experiments seem to show, therefore, that even if *Bacteria* do multiply by means of invisible gemmules, as well as by the known process of fission, such invisible particles possess no higher power of resisting the destructive influence of heat than the parent *Bacteria* themselves possess."

This is, in fact, by far the most satisfactory kind of evidence that can be produced concerning the powers of resisting heat enjoyed by *Bacteria* and *Vibriones*, because it also meets the hypothesis as to their possible multiplication by invisible gemmules possessed of a greater power of resisting heat, and because no mere inspection by the miscroscope of dead *Bacteria* can entitle us positively to affirm that they are dead, even though all characteristically vital or "true living" movements may be absent.

Facts of a very similar nature were mentioned in the same work, strongly tending to show that *Bacteria* and *Vibriones* are also killed at the same temperature in other fluids, such as infusions of hay or turnip. These facts were referred to in the following statement †:—"Thus, if on the same slip, though under different covering-glasses, specimens of a hay-infusion turbid with *Bacteria* are mounted, (*a*) without being heated, (*b*) after the fluid has been raised to 122° F. for ten minutes, and (*c*) after the fluid has been heated to 140° F. for ten minutes, it will be found that in the course of a few days the *Bacteria* under *a* and *b* have notably increased in quantity, while those under *c* do not become more numerous, however long the slide is kept. Facts of the same kind are observable if a turnip-infusion containing living *Bacteria* is experimented with; and the phenomena are in no way different if a solution of ammonic tartrate and sodic phosphate (containing *Bacteria*) be employed instead of one of these vegetable infusions. The multiplication of the *Bacteria* beneath the covering-glass, when it occurs, is soon rendered obvious even to the naked eye by the increasing cloudiness of the film."

(*To be continued.*)

Geological Society, March 12.—Joseph Prestwich, F.R.S., vice-president, in the chair. The following communications were read:—1. Note on some Brachiopoda collected by Mr. Judd from the Jurassic deposits of the East Coast of Scotland, by Thomas Davidson, F.R.S. In this note the author stated that four species of Brachiopoda collected by Mr. Judd were especially worthy of notice, two of them being quite new, and two new to Britain. Three of them were obtained from the equivalent of the Kimmeridge clay, which was the more remarkable as the Brachiopoda of that formation are comparatively few. The new species described were *Rhynchonelle Sutherlandi* and *Terebratula Joassi*, derived, with *Terebratula humeralis* Röm., from the Upper Oolite of Garty in Sutherland; the fourth species is *Terebratula bisuffarcinata* Schlot., from the Lower Calcareous Grit of Bramberry Hill. 2. On Solfataras and deposits of Sulphur at Kalamaki, near the Isthmus of Corinth, by Prof. D. T. Ansted, F.R.S. After noticing the traces of volcanic action east of the Pindus chain, the author described the Solfataras and sulphur-deposits of the neighbourhood of Kalamaki as furnishing indications that there is even now a real though subdued volcanic energy in this part of Europe. 3. On the origin of clay-ironstone, by Mr. J. Lucas, F.G.S. The author commenced by giving a general view of the varieties, chemical composition, and mode of occurrence of clay-ironstone, and suggested that the formation of all the bedded varieties may be explained by the

* See Report in Quart. Journ. of Microscop Science, Oct. 1870.

† Reasons for this opinion have been fully set forth in "The Beginnings of Life," vol. i. 374 *et seq.*; or the discriminating reader may at once find my justification for this expression by reading pp. 58-66 of M. Pasteur's memoir in Ann. de Chim. et de Physique, 1862.

‡ Fuller details concerning these experiments may be found in the little work already mentioned at pp. 51-56, and also in "The Beginnings of Life," vol. i., pp 325-332.

* "Modes of Origin of Lowest Organisms" 1871, p. 60.

† *Loc. cit.* p. 60.

supposition that they originated in peaty or non-peaty lagoons on the alluvial flats of the deltas of the Carboniferous formations, which would present semi-terrestrial conditions, that is to say, a surface exposed to the air but subject to be covered by floods. 4 Note in vindication of *Leptophlœum rhombicum* and *Lepidodendron gaspianum*, by Principal Dawson LL.D., F.R.S. This note accompanied some photographs of the remains of plants referred to, and was in opposition to the identification of these remains with the *Lepidodendron nothum* Unger, as proposed by Mr. Carruthers in his Appendix to Mr. Daintree's paper on the Geology of Queensland.

Zoological Society, March 18, 1873.—The Viscount Walden, F.R.S., president, in the chair.—A communication was read from Mr. R. B. Watson on some marine shells from Madeira, including a new genus of the *Muricidæ*, proposed to be called *Chascax* and a new *Rissoina*, and embracing descriptions of the whole of the *Rissoæ* of the group of islands.—A communication was read from Dr. J. D. Macdonald, F.R.S., on a specimen of *Acanthias vulgaris* and a species of *Galeus*, probably new to science, taken off Flinder's Island, Bass' Straits.—Mr. W. T. Blandford read a paper on the Gazelles of India and Persia. This contained the description of a new species, *Gazella fuscifrons*, founded on a single specimen obtained by the author in 1872, near the edge of the desert of Seistan.—A communication was read from Dr. J. S. Bowerbank, F.R.S., containing the fifth part of a series of memoirs entitled Contributions to a General History of the Spongiadæ.—A communication was read from Mr. Gerard Krefft, C.M.Z.S., containing the description of a new species of crocodile from Queensland, proposed to be called *Crocodilus johnsoni*.—Mr. Edward Bartlett exhibited and gave the description of a new moth belonging to the family Saturniidæ, which had been obtained in the interior of Madagascar by Mr. T. Waters, and which was proposed to be called *Tropæa madagascariensis.*

Mathematical Society, March 13.—Dr. Hirst, F.R.S., president, in the chair.—Prof. Greenhill, of Cooper's Hill College, was elected a member.—Mr. R. B. Hayward read a paper on an extension of the term *area* to any closed circuit in space. In the sense in which the writer employed the term, area is no longer a mere magnitude or a magnitude affected only with the positive or negative sign, but a magnitude affected with direction; in other words it is a *vector*, not simply a *scalar*. The paper concluded with a few illustrations of the use of this extension of the term area.—Other communications were, on the evaluation of a class of definite integrals involving circular functions in the numerator and powers of the variable only in the denominator, by Mr. J. W. L. Glaisher; note on normals and the surface of centres of an algebraical surface, by Mr. S. Roberts, V.P.; and a proof of the proposition that a number which divides the product of two numbers and is prime to one of them will divide the other, by Mr. M. Jenkins (Hon. Sec.).—Notice was taken in NATURE (August 1, 1872) of the formation of a mathematical society in Paris on the plan of the similar societies of London, Moscow and Berlin. This society having forwarded the first number of its "Bulletin," it was agreed to exchange publications.

Chemical Society, March 20, Dr. Frankland, F.R.S., president, in the chair.—Mr. C. W. Siemens, F.R.S., delivered a lecture "On Iron and Steel." The lecturer, after adverting to his former discourse delivered before the Society in 1868, and describing the various experiments he had made to obtain malleable iron direct from the ore, gave an account of the process by which he had succeeded in completely attaining that object. It consists essentially in fusing the ore by means of the most intense heat in a revolving furnace, and then adding the requisite amount of carbonaceous matter to reduce the iron to the metallic state. The malleable iron thus precipitated in the molten mass becomes aggregated into balls by the revolution of the furnace, and can then be easily removed. It is free from sulphur, phosphorus, and other impurities, and dissolves readily in a bath of molten cast iron, producing steel of a quality equal to that made from the best Swedish bar iron.

Anthropological Institute, March 18.—Prof. Busk, F.R.S., president, in the chair. A paper was read by Mr. George Harris, F.S.A., on theories regarding intellect and instinct, with an attempt to deduce a satisfactory conclusion therefrom. The author, after taking a general survey of the opinions on this subject, citing those of Aristotle, Plato, Descartes, Hobbes, Locke, and several other writers, including some modern authorities, proceeded to compare them one with another, and to consider how far certain apparently irreconcileable differences might be considered compatible. The great perfection of the sensitive system in animals he considered to be the main cause of the unerring dexterity with which they engage in various operations connected with their career. And although they differ essentially from man as regards his capacity for abstract studies, it appears difficult to deny to them the possession of an immaterial being of some kind. High authorities, both among philosophers and divines, have attributed to them a future state of existence. Mr. Harris also read a paper on the concurrent contemporaneous progress of renovation and waste in animated frames, and the extent to which such operations are controllable by artificial means. The writer took a general view of the opinions of those who have treated on this subject, more especially the older authorities, citing Galen, Willis, Buffon, Hunter, and Smellie, and referring also to recent articles on the subject in *Fraser's Magazine* and the *Edinburgh Review*. He adverted to the ancient inquiry as to the progress of renovation and waste in all animated frames, as also to the circumstance that certain of these operations were known to be controllable. He analysed the principle of waste and decay in different bodies, and referred to ossification of the bones and deterioration of the blood as contributing to those conditions. As medical science advances these matters might be more perfectly understood. He recommended experiments of various kinds as to the nature of substances, and their effect on bodies animate as well as inanimate, and with regard to animals and plants as well as man.

Royal Horticultural Society, March 19.—Scientific Committee, Dr. J. D. Hooker, C.B., in the chair. Prof. Thiselton Dyer called attention to the discovery by Fankhauser of the prothallial stage of *Lycopodium*. It appears to be almost identical with that of the *Ophioglosseæ*, and consequently altogether different from that of *Selaginella*. It was remarkable that the carboniferous *Lepidostrobus* and *Triplosporites* differed as regards their spores in precisely the same way as *Lycopodium* and *Selaginella*. If the nature of the germination in the two latter must be held to imply systematic diversity, analogy would equally imply it in the case of the two former. But the parallelism would, under these circumstances, be extremely difficult to understand.—General Meeting, W. Wilson Saunders, F.R.S., in the chair. The Rev. M. J. Berkeley commented on the fine collection of *Cycadaceæ* exhibited by Mr. Bull, a well-fruited pot-plant of the Loquat (*Eriobotrya japonica*), and *Epidendrum erubescens*—a Guatemalan orchid rarely seen in flower, which was exhibited by Mr. C. Leach.

Entomological Society, March 17.—Prof. Westwood, president, in the chair.—M. Ernest Olivier was balloted for and elected a foreign member.—The president exhibited a very rare species of *Paussus* from Abyssinia.—Mr. Smith exhibited a box of ants sent from Calcutta by Mr. G. A. J. Rothney, collected principally in the Botanic Gardens. There were many new species amongst them, a complete series of which was to be reserved for the national collection.—Mr. Cole exhibited two boxes of *Bombycidæ* from Natal.—Mr. Bates read a paper on some species of geodephagous coleoptera from China.—Mr. Müller made some remarks on a beetle (*Araeocerus coffeæ*) which had been imported into Basle with some coffee from Java, and that the insect had since become naturalised and might be found in any quantity there. Mr. Müller also remarked on a cargo of ground nuts which arrived in London direct from Sierra Leone, the kernels of which were destroyed by myriads of the larvæ and perfect insects of the *Tribolium ferrugineum*, accompanied by the larvæ and perfect insects of a species of *Rhizophagus* preying on the former.—Mr. Dunning read some further notes on *Atropos pulsatoria*, with reference to Dr. Hagen and Mr. W. A. Lewis. Mr. Bates put some questions to the meeting, suggested to him by Mr. Darwin, with a view to eliciting information as to sexual differences in certain insects, viz., whether any cases had been noticed of sexual differences in the ocellated spots with which certain insects, as the *Bombycidæ*, were furnished, and also as to sexual differences amongst the *Buprestidæ*. A conversation ensued during which Mr. Jenner Weir stated that *Satyrus hyperanthus* had more ocellated spots in the female than in the male; and Mr Butler mentioned that *Drusillus* had double ocelli in one sex. It was also stated that Mr Saunders had detected sexual differences among the *Buprestidæ*.

MANCHESTER

Literary and Philosophical Society, March 4.—Dr. J. P. Joule in the chair.—Mr. Baxendell read the following communication

from Mr. S. Broughton :—It appears there is some doubt as to the existence of ball discharge in thunderstorms. At the request of Mr. Baxendell I communicate an observation of such, seen during the approach of a storm, in 1854 or 1855, when walking from Altrincham to Timperley. Over the edge of a cloud near the east horizon a flash of lightning was seen, and a ball *apparently* the size of one from a Roman candle shot upwards through an arc of 20° or 30°. I cannot say that it went to another cloud, but that would most likely be so, as my attention was taken up watching the progress of the electric ball.—E. W. Binney, V.P., F.R.S., said that shortly after the meeting of the Society on January 21, when he exhibited the singular fossil plants, which were quite new to him at the time, which he thought would have to be placed in a new genus, he had received excellent transverse and longitudinal sections of similar specimens from Professor Renault of Cluny, which were if possible in a more beautiful state of preservation than those found in the carboniferous strata of Lancashire. On February 4, Prof. W. C. Williamson, F.R.S., stated that these specimens were the branches or stems of the well-known genus *Asterophyllites*. Now the French professor states that he had described this fossil plant in a memoir read before the Academy in 1870, and that in his opinion it belonged to *Sphenophyllum*. I am not in possession of the facts from which the two learned professors came to such different conclusions, but I am inclined to consider the singular little stem as belonging to a new genus until the leaves of *Sphenophyllum* or *Asterophyllites* are found attached to it. When this comes to pass of course there can be no doubt on the matter.—The President said that he had made another observation of the position of the freezing poin in the thermometer used in making the observations recorded in the Proceedings for April 16, 1867, and February 22, 1870. The gradual rise of the zero during twenty-nine years was shown by a diagram, the ordinates representing divisions etched on the glass stem, each corresponding to $\frac{1}{12}\frac{}{0}$ of a degree Fahrenheit.—Mr. William H. Johnson, B.Sc., read a paper "On the Influence of Acids on Iron and Steel," in which he showed the general effects of acid; its effects on the weight; on the breaking strain and elongation; effect of pyroligneous acid; effects of acids on copper and brass; and of zinc on iron.

PARIS

Academy of Sciences, March 17, M. de Quatrefages, president, in the chair.—The following papers were read: On the theory of the movement of Jupiter, by M. Le Verrier.—The transit of Venus—method for obtaining the moment of contact by photography, by M. Janssen. The author suggests the use of a photographic plate cut in the form of a disc, and made to revolve. By this means a number of photographs can be obtained with very minute intervals of time between each exposure.—On the heat produced by the mixture of the hydracids with water and on the molecular volumes of their solutions, by M. Berthelot. The acids experimented on were the hydrochloric, hydrobromic, and hydriodic. The author decides that these acids and their compounds give rise to similar amounts of molecular work.—On new applications of the principles of the navigation sluice to oscillating columns of liquid, by M. A. de Caligny.—On a shock of earthquake observed at Florence on March 12, 1873, by M. de Tchihatchef. The shock was observed at 9h. 5m. p.m., it did not last more than half a second, and its direction was S.E. to N.W., bar. 725mm.—M. Secchi presented his memoir "On the Distribution of the Prominences on the Solar Disc, and on the study of the Spots."—On barometic changes and their connection with magnetic variations, by M. J. A. Broun.—New experiments on singing flames, by M. F. Kastner.—Observations on the theory of solar cyclones, by M. E. Vicaire. The author raised several objections to M. Faye's theory of the sun, and promised to explain his own hypothesis shortly; this, he said, was simply that of Wilson.—On "Spectrometry;" Spectronatrometry, by MM. P. Champion, H. Pellet, and M. Grenier. The authors described an instrument for the spectroscopic estimation of minute quantities of sodium. The principle depended on the comparison of a sodium flame in which a known quantity of sodium was being heated with the flame coloured by the substance the sodium in which it was required to know. The apparatus described was somewhat complicated, but the principle upon which it worked was the use of a graduated compensating wedge of coloured glass. M. Janssen made some observations on the process.—Observations on M. Gernez's recent note on the crystallisation of supersaturated solutions, by M. Ch. Violette.—On the methods of increasing the length of bones and stopping their growth, by M. Ollier. On the anatomy of *Comatula rosacea*, by M. Edm. Perrier. On a deposit of fossil mammiferæ near Lapsista, Macedon, by M. Gorceix. "On polyhedric concamerations," by M. G. Perry.

DIARY

THURSDAY, MARCH 27.

ROYAL SOCIETY, at 8.30.—The Radiation of Heat from the Moon, the Law of its Absorption by our Atmosphere, and of its Variation in Amount with her Phases (Bakerian Lecture): Earl of Rosse.
SOCIETY OF ANTIQUARIES, at 8.30.—Election of Fellows.
ROYAL INSTITUTION, at 3.—Coal and its Products: A. V. Harcourt.

FRIDAY, MARCH 28.

ROYAL INSTITUTION, at 9.—Force and Energy: Prof. Clifford.
QUEKETT CLUB, at 8.
ROYAL COLLEGE OF SURGEONS, at 4.—Extinct Mammals: Prof. Flower.

SATURDAY, MARCH 29.

ROYAL INSTITUTION, at 3.—Darwin's Philosophy of Language: Prof. Max Müller

MONDAY, MARCH 31.

LONDON INSTITUTION, at 4.—Fungoid Organisms: Prof. Thiselton Dyer.

TUESDAY, APRIL 1.

ROYAL INSTITUTION, at 3.—Forces and Motions of the Body: Prof. Rutherford.
ANTHROPOLOGICAL SOCIETY, at 8.—Notes on the Collection of Peruvian Skulls and Pottery lately received from Consul Hutchinson: Prof. Busk and Dr. Barnard Davis.—On the Natives of Vancouver's Island: Richard King.—On a Human Skull from Birkdale, Southport: T. M. Reade.
SOCIETY OF BIBLICAL ARCHÆOLOGY, at 8.30.
ZOOLOGICAL SOCIETY, at 8.30.—On the Brain and a portion of the nervous system of *Pediculus capitis*: Dr. J. S. Bowerbank.—Notes on the genera of Turtles (*Oiacopodes*) and especially on their skeleton and skulls: Dr. J. E. Gray.—Descriptions of three new species of Flying Squirrels: Dr. A. Günther.
ASIATIC SOCIETY, at 3.

WEDNESDAY, APRIL 2.

SOCIETY OF ARTS, at 8.—On Economy of Fuel for domestic purposes: Capt. Douglas Galton, C.B.
LONDON INSTITUTION, at 7.—Courts of Special Commercial Jurisdiction: N. H. Paterson
ROYAL MICROSCOPICAL SOCIETY, at 8.—On a new *Callidina* with the result of experiments on the desiccation of Rotifers: H. Davis.—On the Development of the Sturgeon's facial arches: W. K. Parker.

THURSDAY, APRIL 3.

CHEMICAL SOCIETY, at 8.—A way of exactly determining the specific gravity of Liquids: Dr. H. Sprengel.—On Cymene from various sources: Dr. C. R. A. Wright.—Researches on the action of the Copper-zinc couple on organic bodies. II.—On the iodides of Amyl and Methyl: J. H. Gladstone and A. Tribe.—Contributions from the Laboratory of the London Institution, No. XI.—Action of the acid chlorides on Nitrates and Nitrites: Dr. H. G. Armstrong.
LINNEAN SOCIETY, at 8.—On new Indian Fishes: Surgeon-Major F. Day.—On the Fungi of Ceylon: Rev. M. J. Berkeley and C. E. Broome.
ROYAL INSTITUTION, at 3.—Coal and its Products: A. V. Harcourt.

BOOKS RECEIVED

ENGLISH.—Celestial Objects for Common Telescope. 3rd edit.: Rev. T. W. Webb (Longmans).—Elementary Treatise on Wave Theory of Light. 3rd edit.: H. Lloyd (Longmans).—The Childhood of the World: E. Clodd (Macmillan).

ORIGIN OF CERTAIN INSTINCTS

THE writer of the interesting article in NATURE of March 20 doubts whether my belief "that many of the most wonderful instincts have been acquired, independently of habit, through the preservation of useful variations of pre existing instincts," means more than "that in a great many instances we cannot conceive how the instincts originated." This in one sense is perfectly true, but what I wished to bring prominently forward was simply that in certain cases instincts had not been acquired through the experience of their utility, with continued practice during successive generations. I had in my mind the case of neuter insects, which never leave offspring to inherit the teachings of experience, and which are themselves the offspring of parents which possess quite different instincts. The Hive-bee is the best known instance, as neither the queen nor the drones construct cells, secrete wax, collect honey, &c. If this had been the sole case, it might have been maintained that the queens, like the fertile females of humble-bees, had in former ages worked like the present neuters, and had thus gradually acquired these instincts; and that they had ever afterwards transmitted them to their sterile offspring, though they themselves no longer practised such instincts. But there are several species of Hive-bees (*Apis*) of which the sterile workers have somewhat different habits and instincts, as shown by their combs. There are also many species of ants, the fertile females of which are believed not themselves to work, but to be served by the neuters, which capture and drag them to their nests; and the instincts of the neuters in the different species of the same genus are often different. All who believe in the principle of evolution will admit that with social insects the closely allied species of the same genus are descended from a single parent-form; and yet the sterile workers of the several species have somehow acquired different instincts. This case appeared to me so remarkable that I discussed it at some length in my "Origin of Species;" but I do not expect that anyone who has less faith in natural selection than I have, will admit the explanation there given. Although he may explain in some other way, or leave unexplained, the development of the wondrous instincts possessed by the various sterile workers, he will, I think, be compelled to admit that they cannot have been acquired by the experience of one generation having been transmitted to a succeeding one. I should indeed be glad if anyone could show that there was some fallacy in this reasoning. It may be added that the possession of highly complex instincts, though not derived through conscious experience, does not at all preclude insects bringing into play their individual sagacity in modifying their work under new or peculiar circumstances; but such sagacity, as far as inheritance is concerned, as well as their instincts, can be modified or injured only by advantage being taken of variation in the minute brain of their parents, probably of their mothers.

The acquirement or development of certain reflex actions, in which muscles that cannot be influenced by the will are acted on, is a somewhat analogous case to that of the above class of instincts, as I have shown in my recently published book on Expression; for consciousness, on which the sense of utility depends, cannot have come into play in the case of actions effected by involuntary muscles. The beautifully adapted movements of the iris, when the retina is stimulated by too much or too little light, is a case in point.

The writer of the article in referring to my words "the preservation of useful variations of pre-existing instincts" adds "the question is, whence these variations?" Nothing is more to be desired in natural history than that some one should be able to answer such a query. But as far as our present subject is concerned, the writer probably will admit that a multitude of variations have arisen, for instance in colour and in the character of the hair, feathers, horns, &c, which are quite independent of habit and of use in previous generations. It seems far from wonderful, considering the complex conditions to which the whole organisation is exposed during the successive stages of its development from the germ, that every part should be liable to occasional modifications: the wonder indeed is that any two individuals of the same species are at all closely alike. If this be admitted, why should not the brain, as well as all other parts of the body, sometimes vary in a slight degree, independently of useful experience and habit? Those physiologists, and there are many, who believe that a new mental characteristic cannot be transmitted to the child except through some modification of that material sub-stratum which proceeds from the parents, and from which the brain of the child is ultimately developed, will not doubt that any cause which affects its development may, and often will, modify the transmitted mental characters. With species in a state of nature such modifications or variations would commonly lead to the partial or complete loss of an instinct, or to its perversion; and the individual would suffer. But if under the then existing conditions any such mental variation was serviceable, it would be preserved and fixed, and would ultimately become common to all the members of the species.

The writer of the article also takes up the case of the tumbling of the pigeon, which habit, if seen in a wild bird, would certainly have been called instinctive; more especially if, as has been asserted, it aids these birds in escaping from hawks. He suggests that it "is a fancy instinct, an outlet for the overflowing activity of a creature whose wants are all provided for without any exertion on its part;" but even on this supposition there must have been some physical cause which induced the first tumbler to spend its overflowing activity in a manner unlike that of any other bird in the world. The behaviour of the ground-tumbler or Lotan of India, renders it highly probable that in this sub-breed the tumbling is due to some affection of the brain, which has been transmitted from before the year 1600 to the present day. It is necessary gently to shake these birds, or in the case of the Kalmi Lotan, to touch them on the neck with a wand, in order to make them begin rolling over backwards on the ground. This they continue to do with extraordinary rapidity, until they are utterly exhausted, or even, as some say, until they die, unless they are taken up, held in the hands, and

soothed; and then they recover. It is well-known that certain lesions of the brain, or internal parasites, cause animals to turn incessantly round and round, either to the right or left, sometimes accompanied by a backward movement: and I have just read, through the kindness of Dr. Brunton, the account given by Mr. W. J. Moore (*Indian Medical Gazette*, Jan. and Feb 1873) of the somewhat analogous result which followed from pricking the base of the brain of a pigeon with a needle. Birds thus treated roll over backwards in convulsions, in exactly the same manner as do the ground-tumblers; and the same effect is produced by giving them hydrocyanic acid with strychnine. One pigeon which had its brain thus pricked recovered perfectly, but continued ever afterwards to perform summersaults like a tumbler, though not belonging to any tumbling breed. The movement appears to be of the nature of a recurrent spasm or convulsion which throws the bird backwards, as in tetanus; it then recovers its balance, and is again thrown backwards. Whether this tendency originated from some accidental injury, or, as seems more probable, from some morbid affection of the brain, cannot be told; but at the present time the affection can hardly be called morbid in the case of common tumblers, as these birds are perfectly healthy and seem to enjoy performing their feats, or, as an old writer expresses it, "showing like footballs in the air." The habit apparently can be controlled to a certain extent by the will. But what more particularly concerns us is that it is strictly inherited. Young birds reared in an aviary which have never seen a pigeon tumble, take to it when first let free. The habit also varies much in degree in different individuals and in different sub-breeds; and it can be greatly augmented by continued selection, as seen in the house-tumblers, which can hardly rise more than a foot or two above the ground without going head over heels in the air. Fuller details on tumbler-pigeons, may be found in my "Variation of Animals under Domestication," vol. i. pp. 150, 209.

In conclusion, from the case of neuter insects, of certain reflex actions, and of movements such as those of the tumbler-pigeon, it seems to me in the highest degree probable that many instincts have originated from modifications or variations in the brain, which we in our ignorance most improperly call spontaneous or accidental; such variations having led, independently of experience and of habit, to changes in pre-existing instincts, or to quite new instincts, and these proving of service to the species, have been preserved and fixed, being, however, often strengthened or improved by subsequent habit.

With regard to the question of the means by which animals find their way home from a long distance, a striking account, in relation to man, will be found in the English translation of the Expedition to North Siberia, by Von Wrangell. He there describes the wonderful manner in which the natives kept a true course towards a particular spot, whilst passing for a long distance through hummocky ice, with incessant changes of direction, and with no guide in the heavens or on the frozen sea. He states (but I quote only from memory of many years standing) that he, an experienced surveyor, and using a compass, failed to do that which these savages easily effected. Yet no one will suppose that they possessed any special sense which is quite absent in us. We must bear in mind that neither a compass, nor the north star, nor any other such sign, suffices to guide a man to a particular spot through an intricate country, or through hummocky ice, when many deviations from a straight course are inevitable, unless the deviations are allowed for, or a sort of "dead reckoning" is kept. All men are able to do this in a greater or less degree, and the natives of Siberia apparently to a wonderful extent, though probably in an unconscious manner. This is effected chiefly, no doubt, by eyesight, but partly, perhaps, by the sense of muscular movement, in the same manner as a man with his eyes blinded can proceed (and some men much better than others) for a short distance in a nearly straight line, or turn at right angles, or back again. The manner in which the sense of direction is sometimes suddenly disarranged in very old and feeble persons, and the feeling of strong distress which, as I know, has been experienced by persons when they have suddenly found out that they have been proceeding in a wholly unexpected and wrong direction, leads to the suspicion that some part of the brain is specialised for the function of direction. Whether animals may not possess the faculty of keeping a dead reckoning of their course in a much more perfect degree than can man; or whether this faculty may not come into play on the commencement of a journey when an animal is shut up in a basket, I will not attempt to discuss, as I have not sufficient data.

I am tempted to add one other case, but here again I am forced to quote from memory, as I have not my books at hand. Audubon kept a pinioned wild goose in confinement, and when the period of migration arrived, it became extremely restless, like all other migratory birds under similar circumstances; and at last it escaped. The poor creature then immediately began its long journey on foot, but its sense of direction seemed to have been perverted, for instead of travelling due southward, it proceeded in exactly the wrong direction, due northward.

CHARLES DARWIN

UNIVERSITY OARS

II.

WE resume our remarks at the point at which we left off last week, *i.e.* the uncomfortable one of the killed and wounded in the great annual battles on the Thames.

Of the 294 men who rowed in the 26 races taking place between the years 1829 and 1869 (both inclusive), 39 men have died, or rather we should say 40, for one other death has occurred, apparently since the introductory portion of the work was written, and the tables in the appendix were compiled, and we are assured on the authority of elaborate statistics and the logic of averages, that, in comparison with other portions of the civil community, this is a very moderate death-rate. Of the diseases which have carried off in youth or early manhood these 40 men, we will only instance one kind, as being the only one with which boat-racing can presumably be connected, namely consumption, "and other diseases of the chest:" to these perhaps may be added "heart affections." Of the former there are 9, of the latter 3, in all 12.

We are assured, again, that this percentage is a mode-

rate one, that these ailments are still more exacting, not only with other portions of the "civil community," but also with the seamen of the Royal Navy, and with the men who fill the ranks of the army, and notably so of the Guards; it being notorious that men of tall stature are more liable to be attacked by, and less able to resist, diseases of this nature than men of more compact build. But here we must confess that this portion of the book does not leave upon our minds quite so comfortable an impression as we could desire. It is felt throughout that the parties compared have little in common in the essentials that make such comparisons valuable. True the University Oars as a rule are tall, above the average height even of men in their own rank of life; but they are "picked" men—picked for strength as well as stature—picked for physical power already proved—whose whole life from infancy up to manhood has been one varied series of all that art, nature, and science could bring to bear favourably upon their growth and development. While on the other side do we not find the reverse of these conditions prevailing? does not the author himself, elsewhere, describe with painful emphasis the wretched forms, stunted frames, unhealthy occupations and debasing habits of a large portion of the "civil community;" and is it not notorious that soldiers in regiments where height of stature is the chief requisite, were probably throughout their growing time subject to privations in food and clothing and housing, which coupled with rapid growth, and their surroundings after enlistment, presented the very conditions most favourable to the development of the diseases in question?

While expressing an opinion of qualified satisfaction with the comparisons instituted, we can in no way question the accuracy of the figures given; but we must record our feeling, which we believe will be one generally felt, that such evidence fails in accomplishing the purpose for which it was advanced.

We have stated our belief that, could the truth be ascertained, as many or more injuries would be found to have occurred in the same space of time (a similar number of men having been so engaged) in hunting, at foot-ball, or at cricket; probably too as many of these injuries would have proved fatal. But in stating this we are brought face to face with the fact that, in all instances of hurt or of injury so sustained, they would arise from *accidents*. But this is not the case with the injuries which spring from Boat-racing; here, be they trifling or be they severe, be they few or be they many, they seem to be the natural outcome of the exercise itself; not a hurt, in a sense in which we commonly use that word, of bruise, or break, or strain, and to which we may apply support or remedy, but an unknown evil, unfelt, unsuspected, at the time, but to which existence has been given—to be developed in after-life, when we least suspect it, and are least able to cope with its advances. Now the question which presents itself here to us, and must present itself to any one who cares for the continuation of this favourite exercise and yet would free it from this grave drawback—is this: Are these injuries, these evils inevitable? Yes, we answer, at once, and without reservation or qualification, to two points of misconception only is hurt or injury in these contests to be attributed: correct these and this exercise will stand out at once, relieved from all let or hindrance, free, freer than any other, because it is exempted from the *accidents* that lie in the path of others. Correct these, and the tripartite list which Dr. Morgan has supplied of *benefited*, *uninjured*, and *injured*, would be transformed into one uniform list of the first-mentioned only, for every one would be benefited who pursued this pastime.

In the contest which took place on the Thames last week the points which would probably strike an ordinary spectator most forcibly would be these:—first, the length of the course (four and a quarter miles), and second, the shortness of the time in which the boats covered the distance (not quite 20 minutes), and he would probably think that the first was too long, and if he did not actually think that the second was too short (for who admits that a race can be run or rowed too quickly?), he would marvel all the same at its performance, and wonder how men *could* propel a boat over such a long course in such a short space of time. Whether the course could be shortened with advantage, and yet sufficiently test the crews, we will not here discuss, although we think it is open to discussion; and how it is possible to propel a boat over it in the above-mentioned time, is only to be explained by one means, *i.e.*, by a critical examination of the boat itself, and, let us add, a glance at its crew. In the latter he will see eight as fine young men as he probably ever saw in his life before; in the former he will see a machine bearing no resemblance to anything he ever saw afloat, either on river, lake, or sea, or possessing in shape, or size, or bulk, or weight, any of the proportions which other boats possess: so slim for its length, so straight, so sharp! constructed at all points to cleave the water like a knife-blade! fitted out at all points to save every fraction of weight in rowing or steering gear, to utilise and concentrate every ounce of propelling power exerted by the oarsmen from stroke to bow.

Now although the perception of this may to some extent explain the extraordinary rapidity of the race, it will not remove from the spectator's mind the idea of its severity. To him it will still appear that the work will have been tremendous, and he is right: the work *was* tremendous, though not perhaps in the manner or of the kind which he imagines, or of what is commonly understood when the word *work* is used.

"In rowing, as in some other exercises, where the voluntary muscles of the trunk and of the upper limbs are engaged, the breath is "held" in the lungs during the muscular effort, in order to keep the chest distended, or firm, or as it is technically called, "fixed," that these muscles may have firm and unyielding points of attachment during the contractile efforts—fixed fulcra for their levers; and when this is prolonged or repeated over any considerable space of time, it becomes a highly disturbing influence to respiration, and doubly so if the exercise be one which greatly augments the respiratory requirement; for the act of fixing the chest is accomplished by retaining the chest at its point of expansion, when in the natural order of respiration it would be collapsing. And while in ordinary effortless breathing, or in exercises where the lower limbs are solely or chiefly employed, such as walking or running, the inspiration and expiration follow each other in uninterrupted succession—each occupying about the same space of time as the other,

and the two constituting the entire process—in rowing, both these acts are hurried over during that time in which the muscles are relaxed, *i.e.*, towards the close of the stroke, and on the rapid forward dart of the body preparatory to another; when the breath is again held and the chest fixed during the muscular effort. Now in ordinary breathing the rate is, to a full-statured man, from 16 to 20 inspirations per minute, while the racing pace is 40 per minute, or more, and we have seen that the breathing is regulated by the stroke, a breath for each, and these are at 40 a minute! But we have also seen that although there is a breath for every stroke, still the double process of inspiration and expiration does not occupy the whole of even this brief space of time, being accomplished during the momentary muscular relaxation towards the end of the stroke and the forward reach of the body preparatory to another, greatly augmenting the rate at which this double process is performed." Truly the spectator was right in thinking a boat-race to be tremendous work, for so it is, as regards heart and lungs, at any rate.

And now with reference to the second aspect of boat-racing, its demands upon the muscular energies of the body, the aspect which probably the spectator had in view when impressed by the probable amount of "work" of the race. Now will he be relieved or will he be disappointed to learn that the work to be done, the muscular exertion to be undergone, is very slight indeed,—certainly not more than, if so much as, was undergone by any one of the thousands who ran the distance shouting on the banks. Perhaps his examination of the boat and boating gear has prepared him for some such revelation, perhaps it has not, but we can assure him that its accuracy has been proved, not only by our own long personal observations of its mode of action and consequent results upon the frames of the men themselves, but by practical and theoretic tests of the most searching kind, instituted by men of unquestionable ability for the office, and of unquestionable freedom from prejudice or bias.

We have doubted whether this would be a relief or a disappointment to the ordinary spectator; nor have our doubts been restricted to him. Others whose practical knowledge of the art and exercise of rowing is great have also found it embarrassing how to receive this announcement. For ourselves, we regard it as an evil, although not one without a remedy. But not only is the muscular effort altogether disproportionate to that of the organs of circulation and respiration, but inadequate in its amount to develop and sustain to their full capacity the frames of the men engaged therein, when rowing is practised for exclusive exercise: it is found that this muscular exertion, inadequate as it is, is also very irregularly and partially divided, very unequally distributed among the several portions of the body. Thus, we quote again from our former source:—

"A little examination will prove, I think, what at first may not have been surmised, that the legs have the largest share of the work in rowing, for while all other parts employed, back, loins, and arms, act somewhat in detail and in succession, the legs act continuously throughout the stroke, and the individual efforts of each, and the concentrated efforts of all the other parts of the body employed are transmitted through them to the point of resistance—the stretcher. . . . . It will be found also that the stroke is nearly finished before the contractile efforts of the arms are in any degree engaged, namely, when the trunk reaches the vertical line, and they are called in to finish the stroke, and to turn and run out the oar on the forward reach of the body preparatory to another. Rowing thus gives employment to a large portion of the back, more to the loins and hips, and most of all to the legs; but it gives little to the arms, and that chiefly to the fore-arm, and least of all to the chest."

At this point Dr. Morgan's views and our own do not run quite parallel, but the divergence is not so great as at first sight may appear, and almost seems the expression of the impatience of the Oarsman at anything which might be construed as a hint that rowing had a fault or a defect of any kind whatever, than the decision of the Physician on a question which he had considered. It may be a loss sometimes, perhaps, to have more qualifications than one for judging or writing on a given subject. Thus we recognise the physician when he admits the importance of the development of the chest by muscular exertion, admits that in so doing we do not merely increase its muscular coverings, but actually expand the walls of the thoracic cavity, giving ample space for the organs contained therein to perform their all-important functions, nay, that these organs themselves are endowed with increased bulk, vigour, and power by the same means: but here the oarsman crops up, and he contends that all these good things are to be obtained by practice at the oar, for that rowing *does* give this invaluable muscular exertion to the chest. Again, we recognise the physician, acknowledging the substantiated facts of physiological inquiry when he admits that the chest receives its muscular action through the arms; but again the oarsman contends that in rowing the arms *do* have energetic work to perform adequate to this task; nay, that in his own experience, when captain of his college boat, "he has seen the biceps expand and the forearm increase in girth;" the latter probably, but the former—well, they must have rowed in very bad style to cause this development! But scarcely is this avowal made when some doubt as to the propriety of the admission seems to be felt, and the subject is disposed of by the following remark. "This is an inquiry which I do not mean to inflict upon my readers. It is of more interest to the student of anatomy than to the general public," probably this is the case, possibly it is not of great interest to either, but how about the rower? It is with him we are now concerned, and we opine it is to him of very great importance indeed.

While we are engaged in fault-finding we will go as far as the paragraph following that from which we have just quoted, and in which we find the same kind of partial reasoning. He proceeds to say:—

"Let us then consider in what way the chest is affected by bodily labour, when the muscles are called into activity, whether in rowing, or running, or in such a course of gymnastics as is now wisely required for young recruits. We find that, in the first place, the parts more especially exercised acquire additional bulk, grow both larger and stronger; and secondly, we observe that the circumference of the chest is increased, it becomes wider and deeper. I have looked over numerous statistics so tabulated as to show the physical value of gymnastic instruction, and these tables all agree in showing that there is under such circumstances a coincident development both of muscle and of chest."

No doubt "the statistics so tabulated" give the results which the author has seen, for are not such statistics, after being inspected by the medical officers of the army, regularly forwarded to the Adjutant-General of the forces for his information? but what has this to do with boat-racing or running? These three exercises are as different in character and as different in their demands upon the physical energies of the human body in their practice, and in the results of their practice, as it is possible to conceive; and who that had investigated these three modes of muscular exertion would thus run them together for the purpose of showing their value or the results of their practice on the development of the chest? If the development of the chest is mainly due to the muscular exertions of the arms, how can running develop it, unless a man run upon "all fours?" When organising this "course of gymnastic instruction for recruits," we held ever before us a principle precisely the opposite to that which regulates either good running or rowing. In these, *sameness* of action, from the start till the close of the exercise, prevails; in the gymnastic course it is *variety*, the course embracing several hundreds of exercises, requiring different degrees of effort, executed at different rates of speed, employing every portion of the frame, and notably the upper limbs and trunk of the body—exercises all tested and proved to accomplish given results, on thousands of men, and over many years of careful observation, long before they were embodied by us in our military system. These three exercises shou'd be estimated each by itself, and allowed to stand on its own feet. No real or permanent advantage can accrue to any of them by being thus lumped together, the more especially as they are in their nature so dissimilar.

ARCHIBALD MACLAREN

THE EARTH

The Earth: a Descriptive History of the Phenomena of the Life of the Globe. 2 vols., with numerous maps and illustrations.

The Ocean, Atmosphere, and Life. Being the Second Series of a Descriptive History of the Phenomena of the Life of the Globe. 2 vols., with numerous maps and illustrations. By Elisée Reclus. Translated by the late B. B. Woodward, M.A., and edited by Henry Woodward, British Museum (Chapman and Hall 1871 and 1873.)

I.

It is at length beginning to be acknowledged on all hands that no system of education can be pronounced perfect without a recognised position being assigned to the study of science. It cannot, of course, be supposed that in the ordinary *curriculum*, say of a university education, the various subjects of scientific study can obtain that exclusive attention which is required, in order to master them; but it is of the highest importance that, by the introduction and use of suitable text-books, the mind of the youthful and ardent lover of Nature in her various phases should be directed and prepared for entering upon those more minute studies and exhaustive researches in reference to particular subjects in the wide field of scientific inquiry, by which alone he can hope to force Nature to disclose her secrets.

FIG. 1.—The Pyramid Mountain

Such a text-book we have in the work now before us—for these four volumes really form one entire work—a most admirable translation of a treatise on the earth and its phenomena by the eminent French *savant*, M. Elisée Reclus, the result of more than fifteen years' careful study, travel, and research. The translation is by the late Mr. B. B. Woodward, the Queen's librarian at Windsor Castle, and edited since his death by his brother, Mr. Henry Woodward, of the British Museum. Notwithstanding the editor's apology, the work suffers but little from its appearance in an English dress; in fact, the translation has been carried out with such remarkable success, that it possesses all the merits of an original English work. The constitution and phenomena of the planet in which we live are subjects of the deepest interest and importance to us all, and, to the earnest and thoughtful seeker after knowledge, present marvels on a scale of grandeur and magnitude far beyond the comprehension of the mere superficial observer. As M. Reclus says:—

"True enough that the earth is nothing but an almost impalpable grain of dust to the vision of the astronomer scanning the nebulæ in the field of his telescope, but it is,

nevertheless, quite as much worthy of study as any other of the heavenly bodies. If it does not possess magnitude of dimensions, it presents an infinite variety in all its details. Whole generations, living one after the other upon its face, might pass their lives in studying its phenomena, without comprehending all their full beauty. There is not even any special science, having for its aim some portion of the terrestrial surface, or some particular series of its products, which does not present to our *savans* an inexhaustible field of inquiry."

The two first volumes of the work, to which alone we must at present confine our attention, consist of four main divisions—(1) on the earth as a planet, (2) on the land, (3) on the circulation of water, and (4) on subterranean forces. The first division treats of the form, structure, and motion of the earth, explaining with great lucidity the different theories respecting its formation.

M. Reclus then proceeds to give an outline of the geological history of the earth as exhibited by the stratification of rocks. In places where the strata have remained undisturbed by the action of the sleepless forces ever at work upon the earth's crust, it is possible to see the strata in their regular order of succession, giving, as it were, an abstract of the earth's geological history. Probably the most remarkable instance in point is to be found in the "Pyramid Mountain," the sketch of which is taken from the famous "Pacific Railroad Report."

The second division treats of the form and distribution of the continents, and points out the wonderful harmony and analogy which prevail in the configuration of continents and oceans, the arrangement and peculiarities of mountain ranges, the origin of valleys, ravines, gorges, and other depressions of the earth's surface. The question of the origin of mountains and valleys is still, generally speaking, an open one amongst geologists; but, nevertheless, with regard to valleys and ravines, one can in many cases distinctly perceive that their formation is due to the ceaseless action of water through countless ages, mountain torrents cutting their way even through vast mountain chains. Nothing can convey a more impressive idea of the tremendous power of water as a natural agent, than the wonderful cañons of Mexico, Texas, and the Rocky Mountains, where the torrent may be seen rushing along through the incision it has cut out for itself in the hard rock at a depth of several thousand feet between perpendicular walls. The greatest of these cañons, that of the Colorado, is 298 miles in length, and its sides rise perpendicularly to a height of 5,000 or 6,000 feet. Valleys at their commencement usually assume the form of amphitheatres in a degree more or less marked. The most regular in form are to be seen in the Central Pyrenees. "The most remarkable, on account of their vast dimensions and the snow-clad terraces which surround them, are the *oules* (boilers) of Garvarnie, Estaubé, and Troumouse, which the slow action of centuries has hollowed out in the calcareous sides of the mountains of Marboré. Undulating tracts of pasture-land furrowed by torrents, prodigious walls rising to 1,500 or even 2,000 or 3,000 feet in almost perpendicular height, gigantic steps on which whole nations might find room to sit, cascades which either spread out over the precipice and float away in a diaphanous veil of mist, or rush down into the valley like an avalanche; the high summits, glittering with unstained snow, which rear their heads high above the wall of cliffs, as if to look over the inclosure—all these features we find combined far in the recesses of these solitary mountains, so as to render the Pyrenean amphitheatre one of the grandest *tableaux* in Europe." In the third division, on the circulation of water, the author discusses at considerable length the phenomenon of snow-fall on mountain heights, the successive stages through which the snow-field passes into the glacier form, the structure and phenomena of glaciers, subjects towards the elucidation of which Prof. Tyndall has made such valuable contributions. The cause of the intersection of crevasses in glaciers is fully explained. A marginal crevasse, as is well known, first appears in a direction tending up the stream of the glacier; it is then carried round by the current until it inclines in a down-stream direction, and is then intersected by another crevasse opening like the first in an up-stream direction. The process is repeated until the numerous intersecting crevasses form a complete labyrinth.

After several very interesting chapters upon the subject

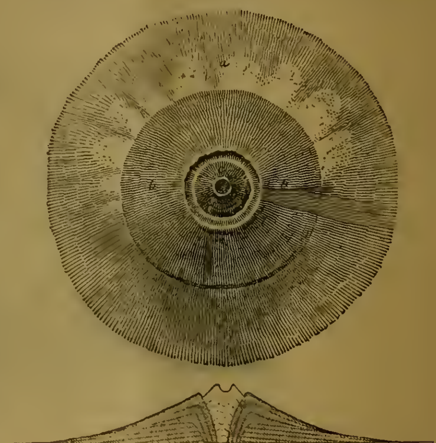

FIG. 2.—Plan and section of the volcano of Rangitoto.—*a* Declivities of tuff; *b* Cone of lava: *c* Pyramid of Scoriæ.

of springs in their different varieties, the remainder of this division is devoted to the discussion of lakes and rivers, and here we find the fact carefully explained and illustrated that the hydrographical systems in different parts of the world exhibit the same relative harmony and order as the forms of the continents. The chapters explaining the process of the formation of deltas, by what are aptly termed "working rivers" (*fleuves travailleurs*), are especially worthy of attention, and will be found to contain a collection of maps and diagrams in illustration of this branch of the subject.

The last division, on subterranean forces, contains some of the most interesting chapters of the whole work, being devoted to the consideration of the most mysterious and appalling of terrestrial phenomena, namely, volcanic eruptions and earthquakes. Science has not yet succeeded in establishing any definite theory respecting the origin of volcanic eruptions, although most valuable con-

tributions have been made to this branch of scientific study by Prof Palmieri, who so courageously stuck to his observatory on Mount Vesuvius throughout the whole of the tremendous eruption of 1872. The symmetrical form of the craters of many volcanoes is very remarkable, in some instances the outline of the cone and crater being absolutely perfect in its symmetry, as in the case of the volcano of Rangitoto, of which a plan and section here reproduced is given in the work.

Our space forbids our entering more fully at present into the merits of these interesting volumes. G. I. F. C.

LETTERS TO THE EDITOR

Dana on Corals

A Reply to the Criticism of Mr. Duncan

In a criticism of Prof. Dana's work on Corals and Coral Islands, printed in a recent number of NATURE (vol. vii. p. 119), Mr. Duncan has seen fit to mention my name and certain of my views adopted by Dana in a somewhat discourteous manner. I therefore beg leave to reply, as briefly as possible, to some of his strictures, which are both erroneous and unjust.

Concerning the general character and plan of Dana's book it is not my intention to say anything, for those are matters which chiefly concern the author and publisher. It is to be presumed that they know, quite as well as any critic, the kind of book demanded by the public—at least by the American public—and experience every day shows the errors of critics in this respect. Certainly few authors have had more extensive and successful experience in writing strictly scientific books for the public than Prof. Dana.

Mr. Duncan criticises the introduction of brief notices and descriptions of "animals which are not corals, and which in no way affect or produce coral reefs or islands," evidently alluding to the Actiniæ, Hydroids, and Bryozoa; for he says, "all the notices and descriptions of the Actiniæ and Hydroidea might have been omitted, as they only confuse the subject." Surely Mr. Duncan ought to know, and if he does, should not ignore the fact, that Millepora, and the allied genera, are true Hydroids, and at the same time form large and abundant corals, which contribute very largely to the formation of coral reefs and islands both in the Atlantic and Pacific Oceans. Moreover, this important fact is stated by Dana on page 104 of his book, and its discovery is correctly attributed to Agassiz, while the animals are illustrated by a cut copied from his figures. It should be added that this discovery, made twenty five years ago, has recently been confirmed by Pourtales ("Deep Sea Corals," p. 56, 1871). That many of the ancient fossil corals were of the same nature scarcely admits of doubt, although the writer has elsewhere shown that this was not the case with all the so-called "Tubulata" Why, then, should this important class of corals be omitted from such a work? As for the Actiniæ, their relationship to the ordinary stony corals is so close, both in external appearance and internal anatomy, that no general work on corals could be considered at all complete without an account of them. Their physiology is also much better known than that of the coral animals. Moreover, they are the only near relatives of the true corals that the majority of the readers of the book will ever see alive.

The Bryozoa are also quite entitled to the page and a half allowed them in this book, for that they do contribute something to the existing coral-reefs can be easily demonstrated. One species of *escharella*, abundant on the eastern coast of the United States, forms solid coral-like masses often two or three inches in diameter, which accumulate in large quantities over wide areas, and, under favourable circumstances, would form limestones of considerable thickness. Some of the coral-reef species grow still larger and occur in profusion. In the Palæozoic coral-seas and reefs the Bryozoa were of still greater importance, and some of the so-called "true corals" of those times evidently belonged to this group in addition to those usually referred to it. The stony Algæ also, are by no means to be ignored in treating of coral reefs, and the half page devoted to them might well have been extended rather than omitted. Darwin, Agassiz, Major Hunt, and others besides Dana, have recognised their agency in furnishing calcareous matter to the reef limestones. Fine specimens of such limestones, composed almost entirely of their remains, may be seen in many American museums.

Mr. Duncan, in criticising Dana for adopting the classification which he believes most natural, makes this remark: "The introduction of American novelties to the exclusion of well-recognised European classifications, is neither right nor scientifically correct." Are we to infer from this that "American novelties" are less valuable than French or English ones, providing they be equally true to nature? Or does our critic prefer European error to American truth? Certainly no one has contributed more, in the way of original investigations and discoveries, to a true classification of the corals than Dana himself, in his great work on the Zoöphytes of the U.S. Exploring Expedition, which was far in advance of any work on this subject that had been written in Europe up to that time (1846). In some respects his classification was far more natural than that proposed afterwards by Edwards and Haime. Unfortunately at that period most of the corals and polyps in European museums had not been described or figured by European writers in a manner accurate enough to make their identification possible, or even, in many cases, to show their generic and family characters. That Edwards and Haime, having access to those collections, and having the benefit of Dana's great work, should have been able to make corrections and improvements was natural. Nor was it less natural that, after the publication of the more accurate descriptions and figures in their works, an American, having these and all the other works at hand, with constant access to the original types of Dana, to the unrivalled collections of corals brought together by Agassiz, and to all the other collections in the United States (by no means few or small) should, after devoting a large part of his time for twelve years to the special study of corals, have been able to make still other corrections and improvements, even in opposition to the views of certain European writers. But several European authors have also made numerous changes in the system of Edwards and Haime, and are likely to make many more. Certainly the time has not yet come when we can consider the classification of corals permanently fixed.

Whether the "novelties" to which he refers be "scientifically correct" is quite another question, and one that must be settled in the scientific way, by the evidence of facts observed, and not by denunciations, nor by dogmatic assertions. In selecting examples of the supposed inaccuracies of my views, as adopted by Dana, Mr. Duncan cites the "Oculina tribe," which the writer has established to include not only the Oculinidæ, but several other families, referred by Edwards and Haime to the Astræidæ and elsewhere. He says—"The admission of Orbicella, which is really the old Astræ of Lamarck (not of 1801), and of Caryophyllia into this well-differentiated tribe, is simply absurd, for they possess structural characters sufficiently diverse as to place them in different families." As a matter of fact, the writer has placed these same corals in different *families* in several papers published during the past five years, and this is the view adopted by Dana; so the argument quoted becomes "simply absurd." Again, he says that "Astrangia was well differentiated long before Prof. Verrill was heard of," and adds that Conrad Lonsdale and "the distinguished French Zoöphytologists consolidated the genus, which has nothing in common with the Oculinidæ." What he means by "consolidated" in this connection, it is difficult to tell, for all that Conrad and Lonsdale did was to describe very poorly, under the name of "Astræ," two or three fossil species, which Edwards and Haime afterwards referred doubtfully to Astrangia. The genus itself was first pointed out by Dana in 1846, and named Pleiadia, as stated in his book, page 68; but it was not at that time strictly defined, for there were no species in the collections of the Exploring Expedition; consequently the name Astrangia, proposed two years later, has been universally adopted. Dana's original specimens, with the MS. names placed upon them in 1845, still exist in our collections. But what my own age or reputation in the year 1848 has to do with the matter is not obvious. I trust that even then I was old enough to have seen the absurdities of such a criticism as that under discussion. That I have, since that time, carefully studied sixteen species of that genus and described a large number of new ones, while only three were known to Edwards and Haime, is true. That I have shown the close relationship between this genus and Cladocora and Oculina is equally true, and I presume that had Mr. Duncan enjoyed as good opportunities as I have had for studying this and all the related

genera he would long ago have arrived at the same conclusions. It is certain that the soft parts of Astrangia, Cladocora, Oculina, and Orbicella are almost identical in all essential points of structure and form, as anyone may see by examining the published figures of the animals of these genera, though the living animals resemble one another much more closely than do the figures. Moreover there are species of Astrangia that bud laterally and grow up into branched forms not unlike Oculina, while the species of the latter are always encrusting while young, and have marginal buds, like the typical Astrangiæ, and some Oculinæ remain permanently nearly in this condition.

Nor do the internal structure of the corals afford any marked and constant characters for their separation. The Cœnenchyma is often nearly wanting in Oculinidæ, though usually characteristic, and it is sometimes present in Astrangiæ, even presenting the radiating surface lines so characteristic of Oculina. In fact it often requires very careful study to determine whether certain specimens belong to Oculina and Astrangia. Such are the genera that have "nothing in common." The relations between Caryophyllia and Astrangia, through Paracyathus, Phyllangia, &c., are sufficiently obvious, and as I have fully discussed all these relations elsewhere (Trans. Conn. Acad. I. pp. 512 to 540, 1869), it is unnecessary to say more upon this point.

What Mr. Duncan means by saying that *Caryophyllia Smithii* was first discovered by the *Porcupine* Expedition in the European seas, is not evident, if he means the well-known species which has passed under that name in all English works, and which Dana illustrates by a figure copied from Gosse's "Actinologia Britannica" (which is the only figure that Mr. Duncan specially criticises). He also finds fault with Dana for saying that *Caryophyllia cyathus* is "widely distributed over the bottom of the Atlantic, even as far north as the British isles," and tells us that "those unrecognised workers have shown that it is not *Caryophyllia cyathus* but *C. clavus* which has the great horizontal range," referring of course to the "workers" who had described the corals of the *Porcupine* expedition. But in Mr. Duncan's paper on those corals (Proc. Royal Soc., 1870, p. 289) he united both those species, together with *C. Smithii* and *C. borealis*, as mere varieties of one species, and makes a long argument to sustain that view, and concludes thus: "I have placed the species borealis in the first place, and regard the old species *C. clavus*, *C. Smithii*, and *C. cyathus* as varieties of it." Dana's statement was doubtless based on Mr. Duncan's assertions, in the paper quoted, that *C. cyathus* and *C. clavus* are identical, and the subsequent discovery of *C. clavus* in the Straits of Florida by Pourtales. The error, therefore, if such it be, belongs wholly to Mr. Duncan, and his remark that "had Dana waited a little longer he would have had the opportunity of quoting correctly," was, to say the least, quite uncalled for, and unbecoming to him. But the peculiar injustice of the critic is, perhaps, best seen in his studied omission of any credit to Dana for his extensive original observations and investigations upon the structure and formation of coral reefs and islands, and his intimations that the facts and theories are mostly borrowed. Thus he says, "The chapters on the structure of coral reefs and islands add little to the knowledge which Darwin and Jukes and Hochsteth have given us; but Dana's great powers of illustration enable him to reproduce the details with which we are so familiar—thanks to these authors—in very engaging forms." Dana has given Darwin full credit and well-merited praise, both in the preface and in many places in the body of the work, for his accurate observations of facts and discovery of the true mode of formation of coral islands; but he also states the well-known fact that his own observations had been made and his report written, in 1842, before the publication of Mr. Darwin's work. The report of Mr. Jukes was published still later (1847). Dana's observations were, therefore, wholly original, and relate mostly to regions not visited either by Darwin or Jukes. The chapters upon this subject are, as they purport to be, mainly a reprint of Dana's original report, with such additions from other and later sources as seemed necessary to make the work complete, all of which are credited to their original authors. In the preface the author says, "The observations forming the basis of the work were made in the course of the Wilkes Exploring Expedition around the world, during the four years from 1838 to 1842." Had Mr. Duncan taken the trouble to examine the original report, he would have found there the true source of most of the facts narrated. The figures of corals were also mostly copied from those in the atlas of his report on zoophytes, which were originally drawn by Dana himself from Nature, so that it is not strange that "some of them are very correct representations of Nature." When the figures are not original, their source has invariably been given. The charge that Dana does not give due credit to others is simply ridiculous, and in no case more so than when he is accused of treating the works of Edwards and Haime with "supreme contempt, inasmuch as he rarely gives them credit for their good work," for in the list (p. 379) of the species of corals described in his great work on Zoophytes, prepared at his urgent request by the writer, he has adopted, without hesitation, all the numerons rectifications made by them, as well as those made by the writer and others. A considerable number of corrections also appear in that list for the first time, and it must, therefore, be quoted as the original authority for such changes. Nothing less than the complete absence of personal vanity and pride, and entire devotion to the advancement of scientific truth, for which Prof. Dana is so justly distinguished, could have induced him to have published such a list in this book. No doubt instances may have occurred in which he has unintentionally overlooked writings of more or less importance. If so, he will doubtless make amends in the next edition. The authority for well-known facts is not always given, because such references would uselessly encumber the book. In other cases, where to mention would be only to condemn, such references have been intentionally omitted when they would have served no useful purpose. Such was the case in respect to the various erroneous European classifications, which were not adopted. Such was also the case when, in describing the extensive coral reefs of Brazil, so well explored by Prof. Hartt, and which were shown by the writer to consist of corals related to and partly identical with those of the West Indies, he does not refer to Mr. Duncan's assertion (Quar. Jour. Geol. Soc. xxiv. p. 30) that "the Orinoco drains a vast tertiary region, and shuts in the coral-life of the Caribbean on the south;" and that "the Florida reefs consist of few species," when more than forty-five species had even then been recorded from them, or more than he admits for any existing reefs. Other statements and theories concerning the recent and fossil corals of the West Indies, in the same paper, have become equally absurd, in consequence of the recent discoveries of Pourtales, and needed no exposure. His assertion that the isthmus of Panama was deeply submerged during the Miocene, and again forcibly urged in his criticism of Dana, may rest on no better foundation than the other assertions just quoted from the same paper, notwithstanding the careless way in which he misquotes, as to place of publication, and misrepresents, as to the contents, a brief article in opposition to that view by the writer. We still look in vain for such proofs as would be afforded by elevated coral reefs having relations to those of the West Indies, but situated on the Pacific side, or even upon the higher parts of the isthmus. The well-known existence of elevated coral reefs in the East Indies and Polynesia, and their presence in the West Indies, known long before Mr. Duncan began to write his valuable papers, proves nothing of the sort. Whatever relations do exist between the fossil corals of the East and West Indies can be easily explained in other ways. We think it singular that while certain geologists find it necessary to force the Gulf-stream across the isthmus during the warm Miocene, others find it quite as important to turn it out of the Atlantic, across the isthmus, during the glacial period. Both assumptions seem equally gratuitous, and may be opposed by numerous facts.

A. E. VERRILL

Animal Instincts

ALLOW me to add two or three facts to the interesting store supplied by your correspondents.

Some years ago a dog was sent to me at Taunton from Honiton, distant seventeen miles. It was conveyed in a closed hamper and in a covered cart. It escaped from my stable on the evening of its arrival, and at 11 o'clock on the following morning it was at its home again. The route lay over a ridge of steep hills.

Mr. Robert Fox, of Falmouth, so well known to the scientific world, is my authority for the following:—The fishermen of Falmouth catch their crabs off the Lizard rocks, and they are brought into the harbour at Falmouth alive and impounded in a box for sale, and the shells are branded with marks by which every man knows his own fish. The place where the box is sunk is four miles from the entrance to the harbour, and that is above seven miles from the place where they are caught. One of these boxes was broken; the branded crabs escaped, and two or three days afterwards they were again caught by the fishermen at the

Lizard rocks. They had been carried to Falmouth in a boat. To regain their home they had first to find their way to the mouth of the harbour, and when there, how did they know whether to steer to the right or to the left, and to travel seven miles to their native rocks?

Another, of which the drover is my informant. Large flocks of sheep are driven weekly from the Welsh hills to the London market. Some time since two escaped in the dark and were supposed to have been stolen. About a fortnight afterwards the two stray sheep reappeared on the Welsh mountains, whence they had been brought. They had found their way through a journey of at least 100 miles. My informant learned from some of the turnpike-gate keepers on the road that, when opening the gate at night to a traveller, two sheep had been seen to rush through.

The nightingale returns from Greece, not merely to the same country, but to the same field and the self-same bush. The swallow takes possession of the same nest.

EDWARD W. COX, Serjeant-at-law

Carlton Club, March 31

The Sociability of Cats

IT may prove of interest to naturalists to record the following curious instance of the social habits of cats:—

I once had two she cats that were upon very intimate terms with each other, always together, and never appeared to have quarrelled. At one time, one of them being about to add an increase to their number, the other very kindly nursed it, and even performed the function of a midwife, and actually attended to the necesary offices that are in ordinary cases attended to by the parent of the progeny. Feeling some interest in curiosities of natural history, I carefully watched my pets, and can therefore vouch for the truthfulness of this extraordinary manifestation of feline sociability.

I may here mention that, as regards the teachableness of cats, I once saw at the house of an intimate friend a fine, large tabby tom-cat put through a drill which would perhaps outvie similar exhibitions of the genus *homo*. He was told to "stand up," "shoulder arms," "present arms," and "stand at ease," which, by observing the hands of the master, he would most obediently do, and with a promptness that was astounding. Another cat was told "to beg," which it at once did by jumping on to a Windsor chair, and performed some curious twistings and rollings that were continued until the morsel of meat was awarded. I have recently introduced a fine kitten to the company of two cats I have had for years. For a long time a deadly feeling of enmity was maintained against the stranger; but now, after a period of three months, the two older cats will not lap their morning's milk until the kitten is in their company; if absent, they actually retire, and refuse to take their meal.

Red Lion Street, March 26 J. JEREMIAH

Manitoba Observatory

HAVING seen in vol. vii. p. 289 of NATURE a statement to the effect that the American Government had established an observatory at Fort Garry, Manitoba, I have to inform you that the so-called observatory is a telegraph reporting station maintained by the Dominion of Canada. Its tri-daily reports, however, in common with those from several other Canadian telegraph stations in correspondence with Toronto, are always placed at the disposal of the Washington weather office.

G. T. KINGSTON

Magnetic Observatory, Toronto, Canada, March 11

ST. THOMAS CHARTERHOUSE TEACHERS' SCIENCE CLASSES

PRIOR to the introduction of Mr. Lowe's revised code, elementary science teaching was always to be found in the curriculum of our best primary schools. The properties of water, the constituents of some of the chemical elements, the first principles of mechanics and the like, were taught with much pleasure by the masters of the schools above alluded to "Payment by results" on the three R's threw cold water upon this class of intellectual teaching, and it has only been revived recently through agitation emanating from enlightened educators. Teachers of late years too have had their studies very much limited by the low requirements of the Education department, and hence many young teachers were launched out into the teacher's profession unable themselves to impart instruction formerly given in our schools. Teachers have long been clamorous for having the standard of education raised in their schools, and have therefore hailed with great satisfaction the act of the Science and Art Department whereby additional grants are given to any pupils or adults or juveniles who could, after receiving a certain number of lessons from a qualified teacher, pass an examination on the subject-matter of these lectures. Teachers, however, before they are permitted to give these lectures to pupils, are required to pass an advanced examination on the subjects they propose to teach. To enable teachers to pass these tests, the St. Thomas Charterhouse Teachers' Classes were inaugurated in October last. The idea was organised by Mr. C. Smith, one of the teachers and organising secretaries, and was carried out under the auspices of the Rev. J. Rodgers, M.A. To the credit of our primary teachers it ought to be added that they have since the promulgation of the idea worked most heartily to bring it to this desired consummation. Profs. Huxley, Ansted, Carruthers, Sir John Bennett, and several other scientific men joined the committee for carrying out the classes. From every part of London masters and mistresses of our elementary schools gladly joined the Science School. Over 230 teachers were initiated, and it is hoped that most of the teachers will qualify themselves in the coming May examination to be able to teach the science subjects they have studied in these classes. Thus from this nucleus it is thought that next year we shall have science classes in connection with nearly every school (elementary) in the metropolis; and undoubtedly in a year or two more the inculcation of elementary general science knowledge will be almost universal.

Science teaching in the hands of a skilful instructor is always popular with young people, and as elementary teachers are eminently successful as collective teachers of the young, who could be better entrusted with imparting instruction which so brightens the intellect as these educators? The chief subjects taken this year at this science school are chemistry, mathematics, acoustics, light and heat, magnetism and electricity, botany (systematic and economic), geology, physiology, plane and solid geometry; but next year the promoters of the scheme hope to have classes in all the twenty-five subjects recognised by the Science Department of the Government. Most of the present students of the classes go in vigorously for physiology, physical geography, and acoustics, light and heat, a great many for chemistry. The teacher of chemistry, Mr. Spratling, has got up a first-rate laboratory for chemical experiments. Mr. Payne, teacher of magnetism and electricity, has all the approved auxiliaries for performing experiments connected with this subject. Next year the biology students will have every facility afforded them for microscopical practice. Mr. Simpson, who has done at least as much as any other person in London to train science teachers, is engaged as the special lecturer on Biology.

During the present session several of our leading scientific men have given a professional lecture to stimulate the teachers in their studies. Dr. Gladstone, Dr. Jarvis, Prof. Ansted, Prof. Carruthers, Mr. Tylor, Rev. W. Panckridge, Prof. Skertchley amongst the number. All the ordinary lectures are given by elementary teachers who have qualified themselves to teach. Two of the students, Mr. Bird and Mr. Powell, who have spent some of their leisure moments in making observations in botanical science, render much valuable aid to their fellow students in furnishing examples to illustrate the lessons given in botany. The students generally are pursuing their studies with great avidity, and as was observed at the Devon Social Society Gathering, by Mr. C. Clarke the importance of these classes cannot be over-estimated

TROGLODYTES OF THE VEZERE*

IV.

IV.—*Arts among the Troglodytes*

THE men of the reindeer age cultivated drawing, chiselling, and even sculpture. We must admit that they had, like ourselves, many inferior artists; but among a large number of coarse attempts, such as our "street

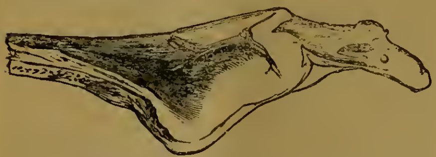

FIG. 23.—Sculptured pointed handle, representing an elongated reindeer.

arabs" chalk on the walls, there are some really remarkable ones, which denote at the same time a clever hand and an eye practised in the observation of nature.

Drawing, with this people, evidently preceded sculpture. The figures in relief are much more rare among them than those that are carved, and likewise much less perfect. The latter are common at the Eyzies and Lower Laugerie, but they abound more especially at the Madelaine, where they are also much more correct. These drawings are all carved. Most of them ornament the

FIG 24. FIG. 25. FIG. 26
Bones of the old man of Cromagnon. Fig. 24—Shin-bone. Fig. 25.—Flattened tibia. Fig. 26—Femur: profile view.

surface of different objects in deer horn, such as batons of command, handles of poignards; but some are engraved on pieces of stone, ivory, or deer horn, which were not intended for any other use, and which were prepared purposely to receive the work of the artist. (See Figs. 12 and 22.)

* Continued from p 369

Nearly all these drawings represent natural objects. Some, however, are merely simple ornate lines, forming zigzag festoons, and more or less elegant curves.

FIG. 27.—Skull of the woman of Cromagnon: profile. The wound in the frontal bone is shown.

Three little roses carved on a handle in deer-horn, seem to represent a polypetalous flower. All the other drawings are representations of animals.

The most numerous are those of the reindeer, then those of the horse: the ox and the aurochs are less common. These different animals are easily distinguished; their ways, their movements are sometimes reproduced with much elegance and accuracy; often they are isolated, dispersed in apparent disorder and in numbers over the whole surface of an object; then again they form groups, they are seen fighting together (see Fig. 22), or fleeing from man.

Of all these drawings, the most important and also the most rare, for it is at present unique, is that which represents the mammoth, and of which I have already spoken.

Drawings of fish are pretty common. With one excep-

FIG. 29.—Skull of the old man of Cromagnon: profile.

tion, which represents an eel or a lamprey (if it is not a serpent), they have a shape which, though not very characteristic, may be intended for a salmon.

The Troglodytes, sometimes so clever in delineating animals, were very inferior artists of the "human form

divine;" they very rarely studied it. Only one study of a head has been found; it is a very small drawing, representing a grotesque profile. Two other drawings, pretty much alike, represent the forearm terminating in a hand with four fingers, the thumb being hidden. I have already told you that the pieces of sculpture are much more rare than the drawings. There are not more than half a dozen, and they all come from Lower Laugerie. One of them, belonging to the Marquis de Vibraye, represents a woman, another represents a reindeer (see Fig. 23).

V.—*Race*

To complete the study of this interesting people, I should now like to be able to characterise the race to which they belonged. The human bones that have been collected up to the present time are not, unfortunately, sufficiently numerous to satisfy our curiosity. However they suffice to prove that this race was very different from the succeeding ones, and to prove above all how much the learned anthropologist Retzius and his disciples were deceived, in stating that all the population of Western Europe, before the comparatively recent epoch of the Indo-European emigrations, belonged to the type of *short heads* or *brachycephals*.

M. Elie Massenat discovered, some months ago, at Lower Laugerie, the skeleton of a man who appears to have been buried in a landslip. But the anatomical description of this precious skeleton has not yet been published; and I regret it the more, that it is the only discovered remains of the Troglodytes of the latest epoch.

The skulls and bones, of which I show you the models, belong to a much earlier date. They were found in the ancient burying ground of the station of Cromagnon, of which the geological, palæontological, and archæological characters have been ascertained with the greatest nicety by M. Louis Lartet. This sepulchre, henceforth celebrated, contained the remains of at least five people. But only three skulls, two male and one female, were sufficiently well preserved to make useful studies. One of the men had attained a great age; the other man and the woman were adults; near them lay a young child. Their stature was very lofty, and far superior to our own. The length of the femur of the old man indicated a height of more than 1·80 m. The volume of the bones, the extent and roughness of the surfaces of muscular insertion, the extraordinary development of the branch of the jawbone, where the masticatory muscles are inserted, prove an athletic constitution.

FIG. 31.

FIG. 28.

FIG. 30.

Fig. 28.—Skull of the woman of Cromagnon front view. Fig. 30.—Skull of the old man of Cromagnon: front view. Fig. 31.—Skull of the old man of Cromagnon, *Norma verticalis*

The tibias, instead of being triangular and prismatic like our own, are flattened like those of the gorilla (see Fig. 24. The upper part of the cubitus, very powerful and arched, supports a very small sigmoidal cavity, and its characteristics again recall the shape of the gorilla. But the conformation of the femur differs radically from that of the monkey tribe. The femur of anthropomorphal monkeys is flattened from front to back—that is to say, much wider than it is thick, and it does not present, on its posterior surface, that longitudinal elevation which in man is called the *rough line*. In the existing human races, the thickness of the femur is in general rather greater than its width, but the difference is inconsiderable. At Cromagnon this bone is much thicker than it is wide (see Fig. 25). The rough line, enormously developed, is no longer a simple elevation; it is a regular bony column, thick and projecting, which considerably augments the solidity of the bone and the extent of the muscular insertions. In this respect, therefore, the Cromagnon race differs much more from the Simian type than do the existing races. The skeletons of these robust Troglodytes bear the traces of their deeds of violence. One of the femurs of the old man presents, towards the lower extremity, a cavity such as is sometimes produced by our musket balls. It is evidently the result of an old wound. It was evidently a human hand, armed with a flint weapon, which produced a long penetrating wound on the skull of the woman. The width of the opening shows that the weapon must have reached the brain. This inglorious murder of a woman does not shed lustre on the people of Cromagnon. The study of their industry has already proved that their social status was not above that of other savage nations. An examination of their skulls confirms this notion,

With them, the sutures of the anterior region of the cranium are very simple, while those of the posterior region are rather complicated; besides which the former have a manifest tendency to close long before the latter. These two characteristics are observable in people and in individuals who live principally an animal life. The Cromagnon Troglodytes were then savages. But these savages were intelligent, and open to improvement; side by side with the proofs of inferiority I have just given, we find among them sure signs of a powerful cerebral organisation. The skulls are large. Their diameters, their curves, their capacity, attain, and even surpass, our medium skulls of the present day. Their form is very

elongated. The alveolar process of the old man is oblique, but the upper part of the face is vertical, and the facial angle is very open. The forehead is wide, by no means receding, but describing a fine curve; the amplitude of the frontal tuberosities denotes a large development of the anterior cerebral lobes, which are the seat of the most noble intellectual faculties. If the Cromagnon Troglodytes are still savages, it is because their surrounding conditions have not permitted them to emerge from barbarism; but they are not doomed to a perpetual savage state. The development and conformation of their brain testify to their capability for improvement. When the favourable opportunity arrives, they will be able to progress towards civilisation. These rough hunters of the mammoth, the lion, and the bear, are just what ought to be the ancestors of the artists of the Madelaine.

I have just glanced over the principal facts in the history of the Troglodytes of the Vézère. For want of time, I have been obliged to shorten several and omit a number more. I hope, nevertheless, that you have been able to follow with me from Moustier to Cromagnon, from Cromagnon to Upper Laugerie and Gorge d'Enfer, and from thence finally to the three stations of the Eyzies, Lower Laugerie, and the Madelaine; the progressive evolution of an intelligent race, which advanced step by step, from the most savage state to the very threshold of civilisation. The Troglodytes of the latest epoch had, so to speak, but one step to take in order to found a real civilisation, for their society was organised, and they possessed arts and industry, which are the two great levers of progress.

This people have, nevertheless, disappeared, without leaving a single trace in the traditions of man. They did not die off by degrees, after having passed through a period of decadence. No, they perished without transition, rapidly, perhaps suddenly, and with them the torch of the arts was suddenly extinguished. Then began a dark period, a sort of middle ages, the duration of which is unknown. The chain of time becomes broken, and when we seize it again, we find, in the place of the reindeer hunters, a new society, a new industry, a new race. They are beginning to understand agriculture, they have some domestic animals, they are raising megalithic monuments, they have hatchets of polished flint. It is the dawn of a new day; but they have lost every remembrance of the arts. Sculpture, drawing, ornamentation, have alike disappeared, and we must descend to the later period of polished stone to find, here and there, on the slabs of some very rare monuments, a few ornamental lines which have absolutely nothing in common with the remarkable productions of art among the Troglodytes. The extinction of the Troglodytes was so complete and so sudden that it has given rise to the hypothesis of an inundation; but against this geology protests, and, to explain the phenomenon, we need only refer to the influence of man himself. Our peaceable reindeer-hunters, with their gentle manners, their light weapons, which were not adapted for fighting, were not calculated to resist the invasion of barbarians, and their growing civilisation succumbed at the first shock, when powerful conquerors, better armed for war, and already provided perhaps with the polished hatchet, came to invade their valleys. It was then seen, as it has often since been proved, that might conquers right.

PROF. FLOWER'S HUNTERIAN LECTURES

LECTURES XVI. XVII. XVIII.

ARTIODACTYLATA. The peculiarities of the skeleton in these animals have been already pointed out; it may be added as a constant special character, that the lower end of the fibula articulates with the calcaneum as well as with the astragalus; the premolars are also simpler than the molars, and there is an extra lobe to the last milk molar. The number of existing species is very great; they tend to divaricate in two directions, one culminating in the Pigs, and the other in the Cavicorn Ruminants. The Hippopotamus and Chevrotain at first sight do not look much alike, but the links between the two are very complete. The existing species are the most differentiated members of the order. Of the *Suina*, the Pigs are very exceptional among existing mammalia in retaining the typical number of forty-four teeth, Gymnura, an insectivorous animal, alone resembling them in this point; however there are spaces between some of them, so they do not form a regular series. The upper canines are very peculiar in being directed upwards instead of downwards, and in the Babirussa, where they pierce the upper lip, this is carried to an extreme. The molars are tuberculated, the tubercles being four in number in the Peccary, but much more numerous, especially in the last molars of *Sus*, where the extra ones represent the third lobe of the same teeth in the Ruminants. In a fossil pig from Pikermé the canines were similarly developed in both sexes, so the sexual differentiation must have been of later origin. In the Wart-hogs the incisors are rudimentary, and late in life the only molars persisting are the enormous columnar last molars; the great size of the canines is well known.

In the true *Ruminantia* there are no upper incisors, and the canines are but rarely developed. In the lower jaw there are eight teeth in a row along the front of the mouth, the two lateral can be proved to be canines, because in older types they are found of a different shape from the six true incisors. The anterior premolar is never developed. Kowalevsky has recently given the names *Bunodont* and *Selenodont* to the non-ruminating and ruminating members of this class, on account of the differences exhibited by their molar teeth, those in the latter presenting the ridges as a double crescent instead of in tubercles. The temporal bone and its surroundings give excellent characters whereby to separate these sub classes; the shape of the glenoid cavity and the direction of the external auditory meatus differing considerably in them. There is also no lateral notch in the palate of the pigs like those in the Ruminants. The Cervidæ and Cavicorn Ruminants also have the odontoid process of the axis peculiarly spout-shaped, whilst in the pigs it forms a simple peg, much as in man. It does not seem to have been remarked before that in this respect the *Tragulidæ* differ from the typical Ruminants, and resemble the pigs, the odontoid in them being a peg. With regard to the feet of *Sus*, Dr. Kowalevsky has made some important observations, having shown that the approximated sides of the two median metacarpals, which are the largest, send in towards one another processes which interlock, and that the shape of their distal articular surfaces causes them to be pressed together when the foot is to the ground. In the pigs the fibula is separate and complete, but in the Ruminants it is represented only by a small piece of bone outside the ankle; a rudiment is sometimes present above. That the deer approach the original type more than do the antelopes is evident from the facts that the upper canines are sometimes present, the crowns of the molars are shorter, and the lateral toes are present, being best developed on the fore-limb. The *Tragulidæ* are less differentiated in having the anterior metacarpals free and the fibula entire, though slender; the canines are well developed in the male at least, and the glenoid cavity is as like that of the pig as of the deer. *Dicotyles* approaches the ruminants from the other side, the metatarsals uniting to form a canon bone, and the foot altogether closely resembling that of Hyomoschus, though an outer toe is lost in the former. The camels are developed in a different direction, approaching the more generalised type.

Artiodactylates appear first in the middle Eocene, and therefore do not go so far back as the Perissodactylata.

Anoplotherium is from the upper Eocene of France and England only; there are two or three species. Though so early a form, it was much specialised, and its peculiarities have not been retained in more modern nor existing forms. It was about the size of the ass. The teeth formed an unbroken series, and, as in man, they were uniform in height. The upper molars were much as in Palæotherium, and the lower were a modification of the same type. Nineteen dorso-lumbar vertebræ were present; the tail was very long, with large chevron bones, which are not found in other Ungulata, and from which Cuvier somewhat rashly inferred that the animal was aquatic. The odontoid process of the axis was simple. In the feet there were only two toes before and behind; the metacarpals were quite separate. In one species there were four toes in front and three behind. *Elotherium* or *Entelodon* is another form from the lowest Miocene. It has been found in the middle of France and in the Mauvaises Terres of Dakotah. Its skull was elongated and somewhat pig-like, but the orbit was completed behind by bone. In size it approached the tapir. The teeth were somewhat carnivorous, the canines being long and bear-like, and the premolars trenchant; the forty-four teeth were present; the posterior molars were comparatively small, and the last one in the lower jaw had scarcely a rudiment of a third lobe. As in Anoplotherium there were only two toes on each foot, and the metacarpals and metatarsals were free.

Of the *Suidæ* many fossil species are known; the first appear in the upper Miocene of Eppelsheim and Pikermé, those in the latter locality much resembling the existing forms, the teeth only being less differentiated. There are no fossil true pigs in America. In the earlier and middle Miocene of Germany and France close allies are found in abundance, with the teeth simpler, only four tubercles being present, and the last molar not being excessively developed. One of these, *Amphichœrus*, had very long canines pointing downwards in the upper jaw. *Hyotherium* comprises *Palæochœrus* and *Chœrotherium*, the latter a small animal described by Leidy. There is a perfect transition between Palæochœrus and the fossil true pigs. Going further back it is doubtful how the line of descent continues. Acertherulum of Gervais may have had some relation to it. The American peccaries are peculiar in having only three premolars; in the fore-foot the outer toe is much reduced, and in the hind foot it is lost: a canon bone is formed by the metatarsals. Fossil peccaries have been found by Lund in Pleistocene caves of the United States, and in the American Miocene, scattered teeth of pig-like animals are not uncommonly met with.

Of recent hippopotamuses there are two species which have been further separated into different genera by Leidy, *Chœropsis* being the smaller and more pig-like; in it also the teeth are not so complicated, and it has two fewer lower incisors. In both genera the molars are very characteristic, being raised in four cusps, each of which in the little worn tooth is trefoiled on the surface; as the tooth gets more used these run together to form ultimately a single insula, undulated at the borders. In the Pleistocene caves and gravels of England, France, Germany, and elsewhere, remains of *Hippopotamus amphibius* are numerous, some are larger than existing individuals, but they do not otherwise differ. In Sicily a smaller species is found in enormous numbers. There are no hippopotamuses in the Miocene nor in the lower Pliocene. In Madagascar a smaller species used to abound. Dr. Falconer, in the Sevalik Hills, found remains of true hippopotamus with four incisors, but most from that region belonged to a distinct form in which all the six were present, and which has been named *Hexaprotodon*. There is no complete bridge between these animals and the pigs, and none have occurred in America.

Dr. W. Kowalevsky has drawn attention to an interesting point in the construction of the limbs of the different members of this class. He has shown that there are two methods by which the extremities may be supported on the carpus and tarsus respectively. In one, the *inadaptive*, the digits as they reduce in number, still are only supported by the carpals which originally articulated with them in the pendactylate foot. In the *adaptive* method, as the digits reduce, they enlarge their bases of attachment on the carpus, and so get a firmer support. This latter condition is found in all existing Artiodactylates except Hippopotamus.

Of the *Selenodonts* one of the earliest known is *Chœropotamus* from the upper Eocene of Montmartre; it was about the size of a pig, with the molars characteristic, presenting five tubercles, three in the anterior row, and two behind. *Anthracotherium* had similar molars, its limbs are unknown. *Hyopotamus* though but little known, was once very abundant; the species varied in size from that of a large rat to that of *Anthracotherium*: it is only found in the Eocene and early Miocene of Europe and North America. The molars were formed on the same principle as those in Chœropotamus, but they were more drawn out; the lower formed double crescents with an internal tubercle well developed; the typical forty-four teeth were present. Most had four toes, and feet very pig-like. Kowalevsky found some at Hordle with only two, and he has named these *Diplopus*. Between Hyopotamus and Anthracotherium there are many intermediate forms. *Xiphodon* with two toes, *Dichobune* and *Cainotherium*, this last had forty-four teeth, forming a continuous row, and three toes on the feet. *Dichodon* was a genus, named by Owen from some teeth, of which it possessed the full number, and the molars formed double crescents. From this we pass by easy transitions to the *Tragulidæ*, which have nothing to do with the Musk-deer, as is so frequently stated. They are at present confined to South Africa, South India, and the adjoining large islands. *Hyomoschus*, the African genus, has survived almost unchanged from the early Miocene period. *Tragulas* is not known fossil.

An American group here comes in to fill a gap. *Oreodon*, an animal about the size of a sheep, found in the early Miocene, is said by Leidy to be quite intermediate between the deer and the peccaries. It had forty-four teeth, its palate more closely resembled that of the deer, and the upper molars formed, as in them, double crescents. The canon bone was not consolidated, and there were apparently four toes. They closely resemble Dichodon. Leidy divides them into three genera, *Agriochœrus*, *Merychyus*, and *Oreodon*. The first of these approaches Chœropotamus, and the crowns of the teeth were very short. *Gelocus*, described by Kowalevsky, is the earliest known form in which the metacarpals coalesced to form a canon bone; it occurs in the Eocene and the earlier Miocene. Those from the former have the metacarpals always free, but in the Miocene they anchylosed in the adult animal, and in higher strata they are fully coalesced. *Dremotherium* was a form which closely approached the deer. *Cervus* proper is first represented in the upper Miocene. In the earliest forms the antlers were very small and simple, closely resembling those of the Muntjac, and having long pedicles; the canines were also developed. All the Cervidæ adhere to the old type in having short crowns and well-marked necks to their molars. The Giraffes (*Camelopardidæ*) are first known from Pikermé and the Sevalik Hills; the molar teeth more closely approached those of the deer than any other animals. *Heladotherium* is not far removed from them; it was of large size and had no horns. *Sivatherium* was the largest of the extinct Artiodactylates. Its bones were bovine in character; the metacarpals and metatarsals coalesced to form a canon-bone, and there were only two toes on each foot; four horns were present, in pairs, apparently cavicorn and yet branched.

Antelopes and Deer coexisted in the Miocene era, but most of the former are Pleistocene in date. The crowns of the molars are prolonged in all the cavicornia. The *Camels* are not directly allied to the other forms; they retain an upper incisor; their molars are in double lunules, and of considerable length. Their geographical distribution is very peculiar, they being confined to North Africa, Arabia, and South America. Dr. Falconer has found their remains in the Sevalik Hills, and Leidy has done the same in North America, naming one of his genera *Procamelus*, and another earlier one Poëbrotherium.

This ends the description of the Artiodactylata, and terminates the course of lectures.

AN ENGINEERING COLLEGE IN JAPAN

THE Japanese Government, as represented by the ambassadors who visited this country last summer and autumn, have resolved upon taking example by our western civilisation, and establishing a college in the city of Yeddo for affording instruction in civil and mechanical engineering to the youth of Japan, as a strong desire has arisen in that country to make an effort to develop the great natural resources which it is known to possess. Our advice and practical assistance in the establishment of the college have been called into requisition, owing to the ambassadors having observed during their sojourn amongst us, how intimately our eminent industrial status as a nation is dependent upon the attention which we devote to the cultivation of those sciences which are involved in the mining, metallurgical, engineering, and many manufacturing industries, and in bringing the forces of nature under the influence of man.

The general scheme of the instruction has been devised by one of our eminent engineers, a gentleman whose experience of Continental and British systems of instruction is very extensive and varied, and judging from the appointment already made, it is evident that the professorial equipment of the college will devolve upon this country. The principal of the college, who is also to be the professor of engineering and mechanics, is Mr. Henry Dyer, M.A. B.Sc., who studied at the University of Glasgow, under the late Prof. J. M. Rankine, Sir William Thomson, and their colleagues. Mr. Dyer was a Whitworth Scholar, and his career hitherto has been one of great and well deserved success. He is well qualified to act as principal of the Yeddo Engineering College.

Prof. Dyer is to be assisted in his duties in the Japanese College of Engineers by professors of mathematics, natural philosophy, chemistry, geology, and mineralogy, and by teachers of English, &c. At least two important appointments have been made, namely, to the professorship of mathematics and to the professorship of natural philosophy. The former has been conferred on Mr. D. H. Marshall, at present assistant to Prof. P. G. Tait in Edinburgh University; and the latter is to be filled by Mr. W. E. Ayrton, formerly of University College, London, and the University of Glasgow. The last-named gentleman has already been employed in the East Indian telegraphic service, and he is at present assistant-engineer in connection with the manufacture of the Great Western Telegraph Cable under Sir William Thomson and Prof. Fleeming Jenkin.

In connection with this Engineering College there are several other points of importance that may be stated. It is intended to institute a geological survey of Japan, and not improbably the active superintendence of that work will devolve upon the gentleman who may ultimately be appointed to the professorship of geology and mineralogy. As an important adjunct to the College, there will be erected a technical workshop, fitted with steam-engine, machine tools, and all the necessary appliances for familiarising the young Japanese engineers with the principles of construction, &c. There will also be a technological museum for the illustration of the progressive stages of various industrial processes from the raw materials to the finished products.

NOTES

LETTERS, dated St. Thomas, appear in the *Times* and *Daily News* from correspondents on board the *Challenger*, where the vessel arrived on March 16. The voyage from Teneriffe had occupied 30 days. The usual programme was to furl sails early in the morning of every alternate day, put the ship under steam, obtain a sounding-haul of the dredge and serial temperatures at every 100 fathoms from the surface down to 1,500 fathoms, then at dusk sail was again made. The sounding line and dredge have been kept constantly going. The former showed that a pretty level bottom runs off from the African coast, deepening gradually to a depth of 3,125 fathoms at about one-third of the way across to the West Indies. If the Alps, Mont Blanc and all, were submerged at this spot, there would still be half a mile of water above them. Five hundred miles farther west there is a comparatively shallow part, a little less than two miles in depth. The water then deepens again to three miles, which continues close over to the West Indies. At the deepest spots both on the east and west side of the Atlantic, the dredge brought up a quantity of dark red clay, which contained just sufficient animal life to prove that life exists at all depths. No difficulty was experienced in obtaining these deep-sea dredgings, and it was merely a question of patience, each haul occupying twelve hours. In depths over two miles little has been found, but that little was totally new. One of the lions of the cruise is a new species of lobster perfectly transparent. Not content with obtaining animals with eyes so fully developed that the body may said to be an appendage, a new crustacean has now dredged up, in which the body has cut itself clear of the eyes altogether, and the animal is totally blind. It has no eyes, or even the trace of an eye. To make up for its deficiency nature has supplied it with the most beautifully developed, delicate lady-like claws, if one may use the term, it is possible to conceive. Nearer the West Indies, in a depth of only half a mile, some similar creatures were brought up, and here the claws, longer than the body, are armed throughout with a multitude of spike-like teeth, looking more like a crocodile's jaw than anything else. At a short distance from Teneriffe, in a depth of a mile and a half, a rich and extremely interesting haul of sponges and coral was obtained, but the latter was unfortuately dead. It is a white species, as large and heavy as the pink coral of the Mediterranean. There are great hopes of obtaining a specimen alive. The nature of the bottom brought up and the way the trawl and dredge frequently catch in being dragged along prove, undoubtedly, that the bottom of the sea, even at great depths, is not so smooth and free from rocks as has hitherto been supposed. A conclusion drawn from this fact is that a considerable movement of the water at the bottom must be going on. The *Challenger* will remain at New York until the 25th of April, and at Bermuda until the mail arriving on the 8th of May, after which she will sail for Madeira, carrying another section line across the Atlantic.

WE have learnt with pleasure that it is contemplated to present a testimonial to Dr. Murie, in recognition of his numerous additions to our knowledge in the field of Biology. From a list before us we learn that Dr. Murie is the author of seventy-five separate works, large and small, mostly connected with zoology. An opinion having been expressed that it might not be inappropriate to present Dr. Murie with a substantial recognition of the services which he has rendered to science by his numerous

memoirs printed in the Proceedings and Transactions of the Zoological Society and other scientific journals, the following gentlemen have already acquiesced in that opinion, and state their belief that Dr. Murie's career has been a most meritorious one, very beneficial to science, and highly honourable to himself. The Viscount Walden, F.R.S., President of the Zoological Society of London, Sir Charles Lyell, Bart., Charles Darwin, F.R.S., Joseph D. Hooker, C.B., F.R.S., Allen Thomson, M.D, F.R.S., G. M. Humphry, M.D., F.R.S., James Glaisher, F.R.S., W. Sharpey, M.D., F.R.S., Wm. Turner, M.B., J. Lockhart Clarke, M.D., F.R.S., W. K., Parker, F.R.S., John Young, M.D., F.R.S.E., F.G.S., George Busk, F.R.S, St. George Mivart, F.R.S., Frank Buckland, F.Z.S., Inspector of Salmon Fisheries, William Aitken, M.D., J. Bell Pettigrew, M.D., F.R.S. Prof. Turner, of the University of Edinburgh, and Dr. Bell Pettigrew, of the Royal College of Surgeons of Edinburgh, have consented to receive subscriptions with a view to furthering the above object. Intending subscribers should communicate with either of these gentlemen.

AT the close of thee winter session of the Class of Physiology in Edinburgh University last Friday, Dr. J. G. McKendrick, F.R.C.P.E., was presented with an address signed by upwards of 400 present and former students of the class. Dr. McKendrick has for the last four years held the office of Demonstrator of Practical Physiology under Prof. J. Hughes Bennett, and during that period the classes in Practical Physiology have increased, from small beginnings, till more than 400 students have been enrolled in a single session. During the last two sessions Dr. McKendrick has conducted the entire work connected with the Chair, in the absence of Prof. Bennett from ill health.

THE government of New South Wales have generously granted 1,000*l.* for the purpose of observing the transit of Venus, and Mr. Russell is taking active measures to provide three stations in that colony with all the requisites for observing the transit, and obtaining at the same time photographs of the planet's position. The three stations will be at Sydney, at Eden, near the south-eastern point of N.S.W., and the third station on the Blue mountains, about fifty miles west from Sydney. Both stations are on telegraph lines, which will be used to determine their longitude. The mountain station has been chosen to avoid, if possible, any chance of cloudy weather, and in the hope that atmospheric difficulties generally will be less.

WE hear with great regret of the death of Dr. Torrey, which took place from pneumonia on March 10. Since the decease of Prof. Darlington he had been the Nestor of American botanists. Torreya, a genus of Taxacea of N. America and N.E. Asia, was named after him. He was a foreign member of the Linnean Society.

THE following has been sent us by a correspondent of M. Riedel:—"The Russian man-of-war *Tsanvina*, Commodore Michel Comancy, is steaming from Ternate to Papua the 28th of November past in search of the missed Russian naturalist, M. Micluha Maclay.—T. G. F. RIEDEL, C.M.Z.S.—Gorontalo, North Celebes, December 30, 187 2."

THE Royal Irish Academy has sanctioned the following grants out of the funds entrusted to it by Parliament for assisting scientific research:—50*l.* to W. H. Bailey for additional explorations at Kiltorcan for fossil plants; 40*l.* to G. H. Kinahan, to assist him in microscopical examinations into the structure of rocks; and 30*l.* to Prof. W. R. M'Nab, M.D., for researches in vegetable physiology.

WE are informed that the Hippopotamus, born a short time ago in the Zoological Gardens at Amsterdam, and which gave some promise of surviving, has, like most of its predecessors, died; so the young "Guy" in Regent's Park, which is doing as well as can be wished, is the only living specimen born and bred in Europe.

PROF. BRÜNNOW, the Astronomer Royal for Ireland, has just issued a second part of his astronomical observations and researches made at Dunsink, the observatory of Trinity College, Dublin. This part contains—New Determination of the Parallax of the Star Groombridge, 1830; Further Investigation of the Parallax of 615 Draconis; Determination of the Parallax of 85 Pegasi; Determination of the Parallax of the * Bradley, 3077; Further Investigations on the Parallax of α Lyræ; Observations of 1830 Groombridge and * (*a*); Observations of 1830 Groombridge, and * (*b*); Observations of 615 Draconis and * (9·5) preceding; Observations of 85 Pegasi; Observations of Bradley 3077 and * (10) following; and Observations of α Lyræ and * (10) following.

THE preliminary report of the U.S. explorations and surveys during the year 1871, in Nevada and Arizona, conducted by Lieut. George M. Wheeler, of the engineer corps, has lately been published in quarto form by the government printer. It contains an account of the plan of the survey, as initiated by Lieut. Wheeler in 1870, and which he has successively continued during the year 1872. The work accomplished during 1871 embraces, among other results, the mapping out of various mining districts, and the determination of the areas, direction, and condition of the lodes. The topographical features of the great Colorado plateau have been developed over the region extending from St. George, in Utah, to the White Mountains near the border line of Arizona and New Mexico, and much information has been gathered as to the geology of this plateau, and of numerous inclosed and interior basins in Nevada. The exploration of the Colorado has determined the absolute limit beyond which a party of examination will not be likely to ascend that river. It has been ascertained that a railroad can cross the Colorado and the mouth of the Virgin River, that it can be carried by easy grades, and that the Colorado can be crossed by a north and south line near the foot of the Grand Cañon.

THE Institution of Naval Architects commences its session for 1873 to-day. The meetings will be held as follows in the hall of the Society of Arts, John Street, Adelphi:—On Thursday, April 3, morning at 12, and evening at 7 o'clock; on Friday, April 4, morning at 12, and evening at 7 o'clock; and on Saturday, April 5, morning at 12 o'clock only. The Right Hon. Sir J. S. Pakington, Bart., M.P., G.C.B., D.C.L., president, will occupy the chair. Judging from the programme of proceedings, this year's meeting ought to be full of interest, and may be productive of important practical results.

THE first report (for 1872) of Governor N. P. Langford, superintendent of the Yellowstone National Park, has just made its appearance, and contains an account of what has been done during the year to protect and preserve this interesting region for the benefit of future visitors. We are informed that new natural wonders are continually discovered, and that the number of geysers, hot springs, &c., is almost countless. The Park was visited during 1872, in connection with the expedition of Prof. Hayden, and new routes determined, by which access will be much easier than heretofore. At present the only mode of approach is by means of saddle and pack trains, and Governor Langford suggests the propriety of constructing several waggon-roads for the convenience of the public. When improvements are made it is thought that extensive settlements will spring up in that region, supported in part by the travel of tourists, and partly by the exportation of lumber made from valuable timber in the district. No mines appear to have been detected, nor is there any prospect of them.

WE have received from the U.S. Engineer Office a well-constructed skeleton map prepared by Lieut. Geo. M. Wheeler, Corps of Engineers, U.S. Army, covering that part of the United States west of the 100th meridian, and exhibiting the relations that exist between lines and areas of explorations and surveys conducted under the auspices of the War Department in that region. It is of interest as showing, in an approximately detailed manner, the routes of government surveys over the large area embraced.

AN excellent opportunity for obtaining a valuable collection of minerals and fossils is furnished by the offer for sale in the U.S. of the celebrated Troost Cabinet, which, indeed, almost belongs to a former generation, having been packed away since the death of its collector at Nashville, Tennessee, a period of over twenty years. It was brought together at a time when rare and choice minerals were more easily obtained than at pressent, by Dr. Troost, who was at the time state geologist of Tennessee, and succeeded in making up one of the finest series of minerals in this country. The collection is at present in charge of Professor J. B. Lindley, of Nashville, to whom communications on the subject are to be addressed.

THE Syndicate recently appointed by the University of Cambridge to inquire into the scheme for establishing a county college at Cambridge have issued their report. While favourable to the scheme generally, they are not prepared to recommend that any special title should at present be offered by the University to students in the manner proposed, or that the University should prescribe rules for the admission of students into the proposed college. They recommend that a general approval be given to the proposed scheme. His Grace the Duke of Devonshire has consented to name the trustees.

THE Marquis of Westminster, K.G., presided at a meeting at Chester on Saturday, in furtherance of a scheme for uniting under one roof the City Library and Reading Room, the Society of Arts, the Architectural and Archæological Society, the Natural Science Society, and also for establishing a local museum, the nucleus of which is already secured to the city by a valuable and extensive collection of geological specimens presented by the Marquis.

THE foundation-stone of the new Presidency College, Calcutta, was laid on February 27 by his Excellency the Governor.

A NEW archæological society has been started at Rajkote, Kattywar, India, named the Sourashtra Society. Its object is the encouragement of antiquarian research, the recording of traditional and ethnological information, and generally to add to the knowledge of the physical, social, and philosophical condition of the Province of Kattywar.

PROBABLY the oldest collection of specimens of natural history now extant in the United States constitutes a portion of the present cabinet of Princeton College, New Jersey. It was first brought together by Monsieur Delacoste, a French collector and naturalist, who flourished in New York at the beginning of the present century, and who published in 1804 a catalogue of his curiosities (chiefly collected in Guiana), filling a pamphlet of about ninety pages. The collection embraces about 260 species of birds, 63 of quadrupeds (which included both mammals and turtles), over 50 of fishes, and other objects in proportion. This collection is still preserved, for the greater part in good condition, at Princeton. The establishment of the Delacoste collection does not antedate that of Peale in Philadelphia; but that long since disappeared, partly by the scattering of the material collected, and partly from its destruction by fire.

COMMANDER SELFRIDGE arrived at Panama on January 21 last, and sailed on the 25th, on board the steamer *Tuscarora*, for the coast of Darien, for the purpose of continuing the survey of the Darien Ship-Canal route. Work will be commenced about latitude 6° 32′ north and be carried across the "divide," following the valley of the river Bajaya, a tributary of the Atrato, to its junction with the latter river, at a distance of about 150 miles from the Caribbean Sea.

MESSRS. BLACKWOOD AND SONS have sent us a well-constructed North Polar Chart, by Mr. Keith Johnston. Besides showing the latest discoveries of voyagers within the Arctic circle, the chart indicates each of the farthest points which have as yet been attained on the margin of the unvisited area, the great glacier and snow fields, the average and extreme limits of the appearance of sea ice, the northmost limits of tree growth on the land, the depths of the Arctic waters, so far as these are known, and the elevation of the land which surrounds them. The political boundaries of the countries which come within the limits of the map are also indicated.

WE have received a copy of the correspondence between the Royal Geographical Society and the Government with reference to the new Arctic Expedition which Government was unsuccessfully petitioned to undertake. The pamphlet contains *in extenso* all the documents submitted to Messrs. Lowe and Goschen, containing information of great intrinsic value.

THE earthquakes in Samos continued in March. A report had been spread by the Smyrniotes that the statement of earthquakes had been invented in the island to draw the Bey back from Constantinople.

ON Feb 20 no less than 20 distinct shocks were felt at Afioom Kara Hissar in Asia Minor, causing great alarm, as there was also almost incessant moving of the earth's surface. On the next day the wind veered round to the north with sharp cold and frost.

ON March 7, at 6 A.M., a smart shock of earthquake was felt at Rhodes.

OUR neighbours on the other side of the Atlantic are continually sending us what they term "Preliminary Descriptions" of novel forms of existing or extinct animals. These consist of new names, followed by short and very imperfect accounts of any apparently peculiar specimens which the author has had the good fortune to hit upon, a note being generally appended to the effect that fuller descriptions will shortly appear in some work now in hand. Our friends seem to forget that the form of ability which gives rise to an illustrious name, is gained by the employment of original method, rather than by the simple recording of novel facts. We fear that the large amount of undigested matter thus brought forward may in the long run produce a condition of dyspepsia of the scientific mind, which will tell hard on the more modest and painstaking workers on the subject, by producing a generally diffused and excessive scepticism as to the value of new discoveries, however promising.

THE "Results of Meteorological and Magnetical Observations, 1872," taken at Stonyhurst College Observatory, show that the meteorological work there is done with great care and minuteness.

WE would recommend to all science teachers the lecture recently delivered by Mr. Joseph Payne at the College of Preceptors, on "The True Foundation of Science-Teaching," now published in a separate form.

THE additions to the Zoological Society's Gardens during the past week include two Barbary Turtle Doves (*Turtur risorius*) from Africa, presented by Mr. G. Hanney; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*), and a Prince Alfred's Deer (*Cervus alfredi*), born in the Gardens; also a White-thighed Colobus (*Colobus bicolor*) from West Africa, purchased.

THE THEORY OF EVOLUTION IN GERMANY *

II.

WE must now examine how the primitive organisms have originated, or rather the single primordial organism from which all others have issued. Lamarck has attempted to solve the problem by his hypothesis of *archigony* or primitive being. Darwin avoids touching this question, doubtless to leave a last refuge for the hypothesis of a creation, and to make a final concession to the spiritualist systems. Haeckel shows no such caution; he is willing neither to renounce the scientific explanation of the phenomenon, nor to abandon the ground of natural philosophy to go astray upon that of faith or poetry; before resigning himself to the incomprehensible, he proceeds to explain, by a mechanical hypothesis, the primordial production of life.

He admits first, as to the origin of the earth, the system of Laplace, of whom Kant, about 1755, was the precursor, in his "Theory of the Heavens." This system is in harmony with all the phenomena at present known, and has not been found to disagree in any single instance. Moreover, it has the advantage of being purely mechanical, and of not requiring a resort to any supernatural force. This theory, consequently, plays the same part in cosmogony, and especially in geology, that the theory of Lamarck does in biology, and especially in anthropology. Both are founded exclusively upon efficient, and not upon final and intelligent causes. Both fulfil the conditions of a scientific theory, and have the same title to universal adoption, until the time when even better hypotheses shall be discovered. Haeckel, however, acknowledges that the theory of Kant and Laplace has a feeble foundation upon two points which it cannot explain—the heat to which is due the gaseous mass which formed the primitive world, and the rotatory movement impressed upon that mass. But every attempt to explain these facts leads us inevitably to the untenable theory of an absolute beginning.

We can no more conceive an absolute beginning for the eternal phenomena of movement than we can imagine an absolute end. The universe is, in the order of space and time, immense and without limits. It is eternal and it is infinite. The great law of the conservation of energy, which has become the basis of all our views of nature, does not allow of any other conception. The world, so far as it is accessible to our knowing faculties, appears to us as an uninterrupted chain of movements which determine a continual change of forms; each form is only the transitory result of a sum of phenomena of motion; but under this change of forms, force remains eternally indestructible.

Life could not commence before the earth had cooled sufficiently to allow the water, which had hitherto been in a state of vapour, to become liquefied and to be deposited on the surface; for all animals and all plants, all organisms in short, consist for the most part only of water combined in a particular manner with other materials. But how is it possible to conceive the commencement of organic life? In answer to this question, Haeckel examines first the relations which exist between organisms and the inorganic kingdom, from the standpoint successively of chemistry, of form, and of motion.

Chemistry teaches us that there does not enter into the material composition of living beings, absolutely any substance, which is not found in inanimate nature. There does not exist any distinct organic matter. The differences which exist between organic beings and the inorganic world cannot then have their essential foundation in the different nature of the substances of which they are composed, but only in the processes by which these substances enter into combination. A greater or less density suffices to place a chasm between two groups of bodies; moreover, the degree of density does not depend upon the component elements, but solely upon the temperature: by heating sufficiently a solid body, we can make it pass first into the liquid, and then into the gaseous state. In contrast to these three degrees of density of inorganic bodies, the solid, the liquid, and the gaseous, Haeckel attributes to living beings a fourth state of aggregation which is proper to them, is neither solid like stone, nor liquid like water, but appears to be a mean between the two, and consists always in a characteristic combination of water with organic matter. This mixed state, which is of the highest importance in the mechanical explanation of the phenomena of life, is explained in its turn, according to Haeckel, by the physical and chemical properties of a simple substance, viz. carbon. This element has a peculiar tendency to form with other elements, in the most diverse proportions of number and weight, complicated and very various combinations. Above all it enters into combination with three other elements, oxygen, hydrogen, and nitrogen, in order to form the indispensable base of all vital phenomena, viz. albumen or protein. Certain very simple organisms, such as the monads, are only small masses of semi-liquid, semi-solid albumen; and it is the same for the most part with other organisms in the earliest stages of their development, when they are as yet only simple cells; albumen then takes the name of *plasma* or protoplasm, and this plasma is now considered as the starting-point of all vital phenomena. Thus it is not more difficult for us to give a general explanation of life than it is to explain the physical properties of inorganic bodies. It is true that ultimate causes are hidden from us; but it is the same in the inorganic world. If we are unable to say why such a combination engenders a cell, no more can we understand why gold crystallises into a tetrahedric or antimony into a hexagonal form. Thus, from a chemical point of view, it impossible to establish any difference between the organic and inorganic kingdoms.

Again, with respect to Form, the simple and homogeneous structure of crystals is opposed to the heterogeneous and complicated structure of living beings; but certain inferior organisms, such as the monads, are formed solely of a small albuminous mass of a structure as simple as that of a piece of silex. Animals and plants thus appear, at first sight, not to have any mathematically determined form like crystals; but Haeckel has pointed out among the *Radiolaria* and many other protozoa a great number of inferior organisms, which, like crystals, may be referred to regular geometrical forms. He has also, in his "General Morphology" (pp. 375—574), presented an ideal system of stereometric forms which explain both the actual forms of inorganic crystals, and those of organic individuals. There is finally a large number of living beings completely amorphous, such as the monads, the *amœbæ*, &c., whose shape is constantly changing, and in which it is as impossible to recognise a determinate form as it is in the case of amorphous inorganic beings, such as non-crystallised stones, precipitates, &c. In respect of form, then, there is no more essential difference between organic and inorganic beings.

Let us now consider Movement. At the present day, as the hypothesis of a vital force is completely abandoned, it is necessary, according to Haeckel, to refer all manifestations of life, and particularly the phenomena of nutrition and reproduction, to the properties of carbon, or at least of hydrogen. With regard to growth, the only difference between living beings and inorganic bodies lies in this, that the former grow in size by intersusception, that is, by the introduction of new particles into their interior, while the latter are enlarged by opposition, by the external addition of new matter. The external conformation is determined, in crystals as well as in organisms, by the laws of adaptation; the form and the size of the crystal depends on the circumstances in which it is placed, on the vessel in which the process of crystallisation goes on, on temperature, on atmospheric pressure, on the presence or absence of foreign bodies. The form of every crystal, as well as the form of every organism, is thus the result of the struggle between two factors,—an internal plastic force proceeding from the chemical constitution of the body, and an external plastic force the result of the influence of the medium. Consequently, if growth and form are processes of life, there is no reason for refusing to attribute life to the inorganic world, as well as to organisms.

As soon as this unity of organic and inorganic nature is fairly established, the problem of primordial or spontaneous generation presents much fewer difficulties. If the attempts which up to the present time have been made to bring about experimentally spontaneous generation have not led to positive results, the only inference to be drawn is, that we are as yet ignorant of the conditions in which it takes place, conditions which, moreover, we may perhaps not now be able to reproduce. It is evident that all the matter which has become organic, would, at the time when the earth was not sufficiently cooled, be mixed in the atmosphere in a form of which we are ignorant. How are we able to reproduce completely in our laboratories all the chemical, electric, and other conditions of that primitive atmosphere? Meanwhile, the combinations of carbon which have already been obtained artificially, give ground for hoping that ere long we shall be able to reproduce the most important of all, the matter of the *plasma* or albumen.

* Continued from p. 352.

But the most powerful arguments in favour of spontaneous generation are furnished by the study of the monads, the simplest of all organisms, which Haeckel has made the subject of a special monograph. Seven species of these are known, some of which live in fresh water, and some in the sea, all of them consisting of small formless masses of albuminous combinations of carbon, and differing from each other only in their mode of reproduction, development, and nutrition. As these living beings do not present any complication of diverse parts, any division of functions or of organs, as all the phenomena of life with them proceed in a homogeneous manner, and without determinate form, it is very easy to conceive of their spontaneous generation. There is indeed one species which even at the present day appears to be born spontaneously, it is that which has been discovered by Huxley, and which has been described under the name of *Bathybius Haeckelii*. It inhabits the sea at depths of from 12,000 to 24,000 feet; it covers the ground sometimes as a network of strings of *plasma*, and sometimes in little heaps. The nucleus of it seems to be formed by a local condensation of albuminous matter, and the monad becomes a cell. As we have seen above that all animals and plants have their starting-point in a cell, it is allowable to suppose that all species are only monads gradually modified by natural selection.

It will be seen that all the views of Haeckel are founded upon the cellular theory as it has been formulated by Schleiden and Schwann. Haeckel always distinguishes two elements—*cytodes* and cells properly so called, reuniting these two elements under the generic name of *plastides*. Cytodes are parcels of plasma destitute of a nucleus, while cells are plastides endowed with a nucleus; each of these two species being subdivided in its turn into two groups, according as they are or are not enveloped by an exterior membrane. Hence there are four forms of *plastides*: (1) Naked or primitive cytodes, like the present existing monads, the only ones which can proceed directly from spontaneous generation; (2) Cytodes with membranes (*lepocytoda*), proceeding from naked cytodes by a coagulation of the exterior portion of the plasma; (3) Naked or primitive cellules by coagulation of an interior portion of the plasma; and (4), Membranous cells, proceeding either from membranous cytodes by interior condensation of the nucleus, or from naked cells by the external formation of a membrane.

There are two theories, one of which may be adopted. Either the monads at present known are descended by propagation from primitive monads and have preserved the same form for millions of years; or, even at this present time, as was the case in the earlier days of organisation, they owe their existence to repeated acts of spontaneous generation. The latter hypothesis is in no respect less probable than the former.

(*To be continued.*)

SCIENTIFIC SERIALS

Journal de Physique Théorique et Appliquée. Par J-Ch. d'Almeida, Prof. de Physique au Lycée Corneille, Paris. We have before us the numbers of the "Journal de Physique théorique et appliquée" extending over the first year of its existence. The object of the journal, which consists of monthly parts of about forty pages each, is stated in the preface to the first number (January 1872) to be the giving of a new impulse to the study of physical science. This its authors aim at doing "by unfolding the more recent and less known theories, by describing the experiments upon which they rest, by indicating the most easy means of repeating them, and by narrating the progress which physical science makes day by day in France and other countries." By the execution of this project "they hope to interest everyone who is acquainted with the principles of science, to enliven teaching, to excite the spirit of research, and to stimulate discoveries." The journal, which is principally mathematical in its treatment of the subjects, differs considerably from such a journal as the "Philosophical Magazine." The original articles in it are few and unimportant. There are criticisms on and reprints of articles selected from other journals, and bearing on the subjects to which this is devoted; but the distinguishing feature of the journal consists in articles, continued generally through several successive numbers, reproducing and elucidating important theories and investigations, which are thus presented in an easily accessible form. Thus the first number starts off with an article on "Electrostatic measures." We also have a series of articles by M. Terquem on electricity and magnetism, beginning in No. 1 with a short article stating the experiments by which it is demonstrated that free electricity resides only in the surfaces of conductors, and then proceeding in No. 2, and subsequent numbers, to treat of the various units employed in measuring quantities of electricity and magnetism, and the relations which exist between them. The reader will gather the character of such articles as those to which we refer, from the following enumeration of the titles of a few others of those which are more important:—"On the action of a magnet on a magnetised molecule at a distance," "On the analogy between the propagation of heat and the distribution of electricity," "On the propagation of permanent electric currents," "On the employment of the wave theory in optical calculations," "On Electrodynamics and the theory of induction" These articles do not contain original matter, nor for the most part do they contain matter arranged in an original way, but they contain useful and concise expositions of the subjects, reproducing such points as the proof of Ampère's theory, Ohm's laws, the method of comparing electro-magnetic and electro-static units, and the like. Such articles will be principally useful to those who cannot obtain the original investigations, or who desire to avoid the labour of consulting those manuals in which these investigations may be included. The journal seems certainly well calculated to extend a knowledge of and interest in the subjects with which it deals, and thus to assist in achieving the end which it proposes to itself.

JAMES STUART

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 20.—"On the Temperature at which *Bacteria*, *Vibriones*, and their Supposed Germs are killed when immersed in Fluids or exposed to Heat in a Moist State." By H. Charlton Bastian, M.D., F.R.S., Professor of Pathological Anatomy in University College, London. (*Continued from p. 413.*)

The facts just cited concerning the behaviour of thin films of turbid infusions which had been heated to different temperatures gave me the clue as to the proper direction of future work. It would seem that when mounted in the manner described, such thin films of infusion continue capable of supporting and favouring the multiplication of any already existing *Bacteria* and *Vibriones*, although, under such conditions, no new birth of living particles appears to take place even in these fluids. The question then arose as to whether, by subjecting larger quantities of the same infusions to any particular sets of conditions, we could ensure that they also should continue to manifest the same properties. Because if so, it would be almost as easy to determine the death-point of *Bacteria* and *Vibriones* when exposed to heat in these infusions, as it had been to determine it for the saline solutions already mentioned.

It was pointed out by Gruithuisen early in the present century that many infusions, otherwise very productive, ceased to be so when they were poured into a glass vessel whilst boiling, and when this was filled, so that the tightly-fitting stopper touched the fluid. Having myself proved the truth of this assertion for hay-infusion, it seemed likely that, by having recourse to a method of this kind, I should be able to lower the virtues of boiled hay and turnip infusions to the level of those possessed by the boiled saline solution with which I had previously experimented—that is, to reduce them to a state in which, whilst they appear quite unable of themselves to engender *Bacteria* or *Vibriones*, they continue well capable of favouring the rapid multiplication of such organisms.

This was found to be the case, and I have accordingly performed upwards of one hundred experiments with inoculated portions of these two infusions raised to different temperatures. The mode in which the experiments were conducted was as follows:—

Infusions of hay and turnip of slightly different strengths were employed. These infusions having been first loosely strained through muslin, were boiled for about ten or fifteen minutes, and then whilst boiling strained through ordinary Swedish filtering-paper into a glass beaker which had previously been well rinsed with boiling water. A number of glass bottles or tubes were also prepared, which, together with their stoppers or corks, had been boiled in ordinary tap water for a few minutes.* They were taken out full of the boiling fluid; and

* The vessels employed have varied in capacity from two drachms to four ounces; some have been provided with glass stoppers and others with very

the stoppers or corks being at once inserted, the vessels and their contents were set aside to cool. When the filtered infusion of hay or turnip had been rapidly cooled down to about 110° F. (by letting the beaker containing it stand in a large basin of cold water), it was inoculated with some of a turbid infusion of hay swarming with active *Bacteria* and *Vibriones*—in the proportion of one drop of the turbid fluid to each fluid ounce of the now clear filtered infusion*. The beaker was then placed upon a sand-bath, and its contained fluid (in which a thermometer was immersed) gradually raised to the required temperature. The fluid was maintained at the same temperature for five minutes by alternately raising the beaker from and replacing it upon the sand-bath. The bottles to be used were then one by one uncorked, emptied, and refilled to the brim with the heated, inoculated fluid.† The corks or stoppers were at once very tightly pressed down so as to leave no air between them and the surface of the fluids. The beaker was then replaced upon the sand-bath and the gas turned on more fully, in order that the experimental fluid might be rapidly raised to a temperature 9° F. (5° C.) higher than it had been before. After five minutes' exposure to this temperature other bottles were filled in the same manner, and so on for the various temperatures the influence of which it was desired to test.

Thus prepared, the bottles and tubes have been exposed during the day to a temperature ranging from 65° to 75° F. And generally one had not to wait long in order to ascertain what the results were to be. In some cases, if the contents of the vessels were to become turbid, this was more or less manifest after an interval of forty-eight hours. In other cases, however, the turbidity manifested itself three or more days later, and the reason of this difference will be fully discussed in a subsequent communication.

For the sake of simplicity and brevity, the necessary particulars concerning the 102 experiments have been embodied in the table which will be found below.

The experimental results here tabulated seem naturally divisible into three groups. Thus, when heated only to 131° F., all the infusions became turbid within two days, just as the inoculated saline solutions had done.‡ Heated to 158° F. all the inoculated organic infusions remained clear, as had been the case with the saline solutions in my previous experiments, when heated to 140° F. There remains, therefore, an intermediate heat zone (ranging from a little below 140° to a little below 158° F.), after an exposure to which the inoculated organic infusions are apt to become more slowly turbid, although inoculated saline solutions raised to the same temperatures invariably remain unaltered. The full explanation of these apparent anomalies I propose to make the subject of a future communication to the Royal Society; meanwhile we may quite safely conclude that *Bacteria*, *Vibriones*, and their supposed germs are either actually killed or else completely deprived of their powers of multiplication after a brief exposure to the temperature of 158° F. (70° C.).

This evidence now in our possession as to the limits of "vital resistance" to heat displayed by *Bacteria*, *Vibriones*, and their supposed germs in neutral saline solutions, and in neutral or acid organic infusions, is most pertinent and valuable when considered in relation to that supplied by other sets of experiments bearing upon the all-important problem of the Origin of Life. These latter experiments alone may possibly leave doubt in many minds; but the more thoroughly they are considered in relation to the evidence brought forward in this communication, the more fully, I venture to think, will every lingering doubt as to the proper conclusion to be arrived at be dispelled.

Thus, we now know that boiled turnip- or hay-infusions exposed to ordinary air, exposed to filtered air, to calcined air, or shut off altogether from contact with air, are more or less prone to swarm with *Bacteria* and *Vibriones* in the course of from two to six days. But, placed under slightly different conditions such as were employed in the inoculation experiments above quoted, although infusions of the same nature do not undergo "spontaneous" putrefactive changes, yet when living *Bacteria* and *Vibriones* are added and not subsequently heated, putrefaction *invariably* takes place and the fluids thus situated rapidly become turbid. There is therefore nothing in the conditions themselves tending to hinder the process of putrefaction, so long as living units are there to initiate it. Our experiments now show that as long as the added *Bacteria*, *Vibriones*, and there supposed germs are subjected to a heat not exceeding 131° F. (55° C.), putrefaction invariably occurs within two days, whilst, on the contrary, whenever they are subjected to a temperature of 158° F. (70° C.) putrefaction does not occur. To what can this difference be due, except to the fact that the previously living organisms which, when living, always excite putrefaction, have been killed by the temperature of 158° F.? It would be of no avail to suppose that the absence of putrefaction in these latter cases is due to the fact that a heat of 158° F., instead of killing the organisms and their germs, merely annuls their powers of reproduction, because in the other series of experiments (with which these have to be compared) where similar fluids are exposed to ordinary or purified air, or are shut off from the influence of air altogether, the most active putrefaction and multiplication of organisms takes place in two, three, or four days, in spite of the much more potent heat of 212° F., to which any pre-existing germs or organisms must have been subjected. The supposition, therefore, that the *Bacteria*, *Vibriones*, and their germs were not killed in our inoculation experiments at the temperature of 158° F., but were merely deprived of their powers of reproduction, would be no gain to those who desire to stave off the admission that *Bacteria* and *Vibrones* can be proved to arise *de novo* in certain cases. Let us assume this—which is indisputably proved by these inoculation experiments—viz. that an exposure to a temperature of 158° F. (70° C.) for five minutes deprives *Bacteria*, *Vibriones*, and their germs of their usual powers of growth and reproduction—that is that it reduces them to a state of potential, if not necessarily to one of actual death. What end would be served by such a reservation? The impending conclusion would not be staved off by means of it. The explanation of what occurs in the other set of experiments, where the much more potent heat of 212° F. is employed, still would not be possible without having recourse to the supposition of a *de novo* origination of living units, so long as those which may have pre-existed in the flask could be proved to have been reduced to such a state of potential death. It would be preposterous, and contrary to the whole order of nature, to assume that the vastly increased destructive influence of a heat of 212° F had restored vital properties which a lesser amount (158° F.) of the same influence had completely annulled.

The evidence supplied by these different series of experiments in whichever way it is regarded, as it seems to me, absolutely compels the logical reasoner to conclude that the swarms of living organisms which so often make their appearance in boiled infusions treated in one or other of the various modes already proved to be either destructive or exclusive of pre-existing living things, are the products of a new brood of "living particles," which, in the absence of any co-existing living organisms, must have taken origin in the fluid itself. For this mode of origin of living units, so long spoken of and repudiated as "spontaneous generation," I have proposed the new term Archebiosis.

Inoculation Experiments made with the view of ascertaining the Temperatures at which Bacteria, Vibriones, *and their Supposed Germs are killed in Organic Infusions.*

NEUTRAL HAY INFUSION.

Temp. to which exposed.	Number of Experiments made.	Date of Turbidity, if any.	Results at Expiration of the 8th day.
122° F. (50° C.)	1	24 hours	Turbid.
131° F.	7	48 hours	All turbid.
140° F.	9	1 in 48 hours 6 in 60 hours 1 in 3 days 1 in 8 days	All turbid.
149° F.	4	2 in 5 days 1 in 8 days	Three turbid. One clear.
158° F.	15	... ...	All clear.
167° F.	4	... ...	All clear.
176° F. (80° C.)	12	... ...	All clear.

tightly fitting corks; and the latter I find have answered quite as well as the former On the whole I have found tightly corked 1 oz. phials to be about the most convenient vessels to employ in these inoculation experiments.

* It was found desirable to filter the infusions after they had been boiled, because the boiling generally somewhat impaired their clearness.

† At this stage, of course, *very great care* is needed in order to avoid all chance of accidental contamination either with living organisms or with unheated fragments or particles of organic matter.

‡ In the experiments already referred to.

ACID TURNIP INFUSION.

March 27.—"On the Radiation of Heat from the Moon, the Law of its Absorption by our Atmosphere, and its variation in amount with her Phases." By the Earl of Rosse, D.C.L., F.R.S.

In this paper is given an account of a series of observations made in the Observatory of Birr Castle, in further prosecution of a shorter and less carefully conducted investigation, as regards many details, which forms the subject of two former communications* to the Royal Society. The observations were first corrected for change of the moon's distance from the place of observation, and change of phase during the continuance of each night's work, and thus a curve, whose ordinates represented the scale-readings (corrected) and whose abscissæ represented the corresponding altitudes, was obtained for each night's work. By combining all these, a single curve and table for reducing all the observations to the same zenith-distance was obtained, which proved to be nearly, but not quite, the same as that found by Professor Seidel for the light of the stars. By employing the table thus deduced, and also reducing the heat-determinations obtained on the various nights for change of distance of the sun, a more accurate phase curve was deduced, indicating a more rapid increase of the radiant heat on approaching full moon than was given by the formula previously employed, but still not so much as Prof. Zöllner's gives for the moon's light.

By employing Laplace's formula for the extinction of light in our atmosphere, the heat-effect in terms of the scale-readings was deduced, and an approximation to the height of the atmosphere attempted.

From a series of simultaneous measurements of the moon's heat and light at intervals during the partial eclipse of November 14, 1872, when clouds did not interfere, it was found that the heat and light diminish nearly if not quite proportionally; the minimum for both occurring at or very near the middle of the eclipse, when they were reduced to about half their amounts before and after contact with the penumbra.

PARIS

Academy of Sciences, March 24.—M. de Quatrefages, president, in the chair. M. Faye read a long and exhaustive reply to M. Vicaire's criticisms on his solar theory and attempted revival of Wilson's hypothesis. He answered each objection in detail, and maintained that his position had not been affected by M. Vicaire's arguments.—M. Berthelot read a paper on the constitution of the solutions of the hydracids, and on their inverse reactions. He believes that the increase of heat evolved with increased dilution proves the existence of a number of hydrates, and that the quantity of hydrated acid required to precipitate certain chlorides from their solutions will throw more light on this point.—On certain propyl new derivatives, related to the metallic propyl compounds, by M. A. Cahours.—M. Th. Lestibondois read a note on certain anomalous lianas.—Papers were read on the conditions under which certain periods of the quadratics of a curve of m degrees disappear or become infinite, by M. Max Marie.—On a new double-image micrometer, by M. C. Noel.—On the measurement of the chemical effect of solar light, by M. E. Marchand.—On Phylloxera, &c., by M. L. Faucon.—On a new method of determining the position of the nodal surfaces in masses of vibrating gas, by M. D. Gernez.—On the volumetric estimation of carbonic anhydride, by M. Houzeau. The author has devised a method for the application of volumetric analysis to the determination of CO_2 in agricultural chemistry. The process consists in absorbing the gas in soda solution containing zincic oxide, precipitating the carbonate formed with neutral solution of baric chloride, and titrating the free soda left with standard sulphuric acid.—Researches on trichloracetic acid and the trichloracetates, by M. A. Clermont.—On the bursting of the skin of fruits exposed to persistent rain, &c., by M. Joseph Boussingault. The author finds that this is due to the diffusion of water into the fruit. Many kinds of fruit thus absorb large quantities of water, and ultimately burst. The author has also experimented on leaves and stalks. In every case sugar diffused out of the fruit and leaves.—On the snow-line, and its elevation in different parts of the world, by M. Ch. Grad.—On M. Pasteur's process for silk-worm preservation, by M. Guisquet, was an answer to M. Guérin-Méneville, who has denied M. Pasteur's statements.—On the phenomena of hibernation presented by flies exposed to successive changes of heat and cold in Russia, by M. Goubareff. Flies found perfectly torpid became lively at + 33° Réaumur, and became again torpid when the temperature was allowed to fall.—On an optical phenomenon produced by the condensation of dew on grass, by M. J. Leterme.

INSTINCT

THE very valuable contribution to Psychology made by Mr. Spalding in his paper on Instinct (*Macmillan's Magazine* for February), and the letters and article which have lately appeared in this Journal, will no doubt stimulate research, and lead to some rational explanation of what bas hitherto been enveloped in a mist of metaphysics. Mr. Spalding has not only proved himself an acute thinker, he has shown a rare ability in devising experiments, and we may fairly expect that his researches will mark an epoch. I am the more grateful to him because his instructive results, though seeming to contradict, do really furnish experimental confirmation of the views put forth in my work, now in the press, wherein it is argued that Instinct is *lapsed* Intelligence: that what is now the fixed and fatal action of the organism, was formerly a tentative and discriminating (consequently intelligent) action: in a word that what is now a connate tendency was formerly acquired experience.

There is great need of precise definition of terms. What is Instinct? What is Experience? What is Intelligence? Twenty different writers indicate twenty different things by these terms. They do not distinguish between Instinct and Impulse; between Experience acquired by the individual, and Experience transmitted from ancestors; between Intelligence, the discernment of Likeness and Unlikeness in feelings, and Intellect, the discernment of Likeness and Unlikeness in symbols. Above all they seldom make clear whether they are treating any fact from the psycho*logical* or from the psycho-*genetical* point of view, *i.e.* whether they are describing the Anatomy or the Morphology of the Mind. It is, for instance, one thing to affirm that our perception of Space is a perception necessarily conditioned by our organism, and in that sense *à priori*; another thing to affirm that this conditioned structure is itself the evolved result of ancestral experiences of Sight, Touch, and Motion, and in that sense the perception of space is *à posteriori.* The point of difference between the empirical and nativistic schools may be got rid of by such a precision in the question. The vital point will then be between the advocates of evolution and the advocates of creation. Those who hold that the Organism is evolved, must hold that its perceptions (and instincts) are evolved through Experience. Those who hold that the Organism is created, and was from the first what we see it now, must hold that its perceptions (and instincts) are pre-ordained, and have no experiential origin whatever.

Having thus cleared the ground of a mass of obstruction, we may now approach the subject of Instinct. In what sense can it be said to be dependent on Experience? Obviously this cannot be answered till we are agreed on the meaning to be assigned to the term Experience. I have defined it the *registration* of Feeling. And what is Feeling? It is reaction of the sentient Organism under stimulus. This reaction has obviously two factors: the structure of the organism, and the nature of the stimulus. It is not every response of the organ that can be a feeling, it is not every feeling that can be an experience. The secretion of a gland is a response, physiologically similar to the response of a sensory organ; but the former is not a feeling, although it enters as an element into the mass of Systemic sensation; and the response of a sensory organ, although a feeling, will not be an experience unless it be *revivable;* and this revival requires that it should be *registered* in the modification impressed on the sentient structure. It is true that rigorously speaking no body, not even an inorganic body, can be acted on without being modified; every sunbeam that beats against the wall *alters* the structure of that wall; but these minute alterations are not only inappreciable for the most part, by any means in our power, they are also mostly annulled by subsequent alterations. In one sense, therefore, no impression ever excites Feeling without modifying the sentient structure; but some impressions, especially when iterated, produce definite and permanent modifications; and these are registrations capable of revival, *i.e.* of the feelings registered, so that when the organism is stimulated its reaction will be determined by those past reactions, and the product will be a feeling more or less resembling the feelings which were formerly produced. Thus we have Feeling as the reaction of the Organism; and the Organism itself as a structure which has been modified by its reactions on external stimuli. What the structure of the Organism is at any stage determines what will be the kind of sentient reactions it will have. Experience is the registration of Feeling, registered in those modifications, which, because they are modifications of structure, must have corresponding activities of Feeling, and from these spring Actions. To trace the history of these modifications or their feelings is Morphology or Psychogeny; to describe their results is Anatomy or Psychology.

We cannot be in doubt then whether Instinct is or is not dependent on Experience; we can only ask: Is a particular action characteristic of a particular animal species, one that the animal has itself *learned* to perform through the adaptation of its organs, under the guidance of sensible impressions reviving the past impressions of *its* experience; or an action inevitably determined by the reactions of the structure inherited from ancestors, so that sensible impressions revive ancestral experiences registered in the modifications impressed on the structure? The answer in each case can only be approximative; and for this reason: until the organism has the requisite degree of development for the performance of the actions, there can be no manifestation of the instincts, and there are few of the instincts manifested at birth.

How, then, shall we define Instinct? How separate the actions which are congenitally determined, from those which are incidentally determined? Both require the indispensable conditions of an appropriate structure and appropriate stimuli. It is obvious that we cannot fix upon the structure alone; and yet the congenital tendencies of that structure must be taken into account; for we see instincts not manifested until long after many other actions have been acquired—as in the case of the sexual instinct. But if congenital tendencies sufficed, we should call the flowering of plants at their normal season when transplanted to a *different* climate, an instinct. Many would say that an action common to an entire

group of animals must be an instinct, since it could not be acquired through individual experience. But how if the conditions of acquisition are also common to the whole group? Thus an infant certainly learns to scratch itself; since, however it may itch, some considerable experience is necessary before it learns to localise the sensation. As, however, the conditions of this acquisition are common to all children, all learn to scratch themselves. Now in many animals this is an inherited acquisition; they scratch themselves from the first. Whether the infant also inherits a structure which would develop into one as apt as that of the animal, cannot be ascertained; all we know is that the infant's nervous structure is too immature at first to permit the localisation of sensation. How much of the subsequent aptitude is the result of congenital tendency, and how much of acquisition through incidental experiences acting on a predisposed organism, cannot be estimated.*

That we require some character to distinguish the instinctive from the impulsive actions, may be readily shown. No one calls Breathing, Secretion, Excretion, &c., instincts. Yet these are the actions of congenital tendencies in the organism. "A hungry chick," says Mr. Spalding, "that never tasted food, is able on seeing a fly or spider for the first time, to bring into action muscles that never were so exercised before, and to perform a series of delicately adjusted movements that end in the capture of the insect." Every one would pronounce this a typical case of Instinct. Now compare with it the following, which no one would class among the instincts: A new-born animal that has never breathed before is able on first feeling the stimulus of the atmosphere to bring into action a very complicated group of muscles which never were so exercised before, and to perform a series of delicately adjusted movements which end in the aëration and circulation of the blood.

This contrast may lead us to the character sought. Understanding that every line of demarcation in psychical phenomena must be more or less arbitrary, and only justified by its convenience, we may draw such a line between Impulse and Instinct. Impulses are the actions which from the first were fatal, inevitable, being simply the direct reflex of the stimulated organs. Given the respiratory organs and the atmosphere, Respiration is the inevitable result. Given the secretory organ and the plasma, Secretion is the inevitable result. There is no choice, the action either takes place or it does not.

Instincts *are* also fatal, inevitable, but they *were* not always so; the element of choice intervenes; and although the intelligent discrimination may be *almost* entirely lapsed, it never is wholly lapsed. The guiding sensation is still discriminative, selective. Hence instincts vary with varying conditions. Thus the *nutritive impulse* which when unsatisfied causes the uneasiness of desire, and which moves the animal in search of food, is markedly distinguishable from the *instinct* which selects the appropriate food and rejects all the rest. If an animal eats only certain kinds of food, out of many which would be nutritious, it is because these kinds have been selected by it, or by its ancestors. Every chicken, Mr. Spalding assures us, has to learn not to eat its own excrement. "They made this mistake invariably, but they did not repeat it oftener than once or twice." He also has this remark:—"Chickens, as soon as they are able to walk, will follow any moving object; and when guided by sight alone they seem to have no more disposition to follow a hen than to follow a duck or a human being. Unreflecting onlookers when they saw chickens a day old running after me, and older ones following me miles and answering my whistle, imagined that I must have some occult power over the creatures, whereas I simply allowed them to follow me from the first. There is the instinct to follow; and, as we have seen, their ear, prior to experience, attaches them to the right object."

I should rather say, "there is the *impulse to follow*: and the instinct to follow the mother, or a duck, or the master who feeds them, is the selected action which becomes rapidly an organised habit." It is one of the conclusions of my work that all our involuntary and automatic actions, were originally voluntary, and that all instinctive actions were originally intelligent. In the case now under consideration, the impulse to follow is a fixed tendency; the instinct to follow is facultative at first, and becomes fixed by habit, but is always, even when most firmly fixed, guided by discriminating feeling.

To conclude: where there is no alternative open to an action it is impulsive; where there is, or originally was, an alternative, the action is instinctive; where there are alternatives which may still determine the action, and the choice is free, we call the action intelligent.

GEORGE HENRY LEWES

* The examples of dogs and horses finding their way home, however marvellous, cannot be affiliated on Instinct, since it is very far from common to the species: for one dog who finds his way home, hundreds are helpless when lost.

HANDBOOK FOR THE PHYSIOLOGICAL LABORATORY

Handbook for the Physiological Laboratory. By E. Klein, M.D.; J. B. Sanderson, F.R.S.; M. Foster, F.R.S.; and T. L. Brunton, M.D., D.Sc. (Churchill.)

STUDENTS of chemistry have, for a long time, by means of the works of Fresenius and others, had the opportunity, almost unaided, of verifying for themselves most of the experimental results of which they hear in lectures, and read in text-books; and thus many are able, before they have finished their educational course, to obtain a thorough practical knowledge of the science. Such has not been the case with regard to physiology; the subject is less advanced, and has progressed more slowly; perhaps this is because the descriptions of the methods by which the ends have been arrived at, as given by lecturers and writers, are incomplete and insufficient. The work before us is the first important attempt that has been made to put the commencing physiologist in a fair position to begin original work on the subject, by giving him the necessary directions for himself performing many of the fundamental experiments on which the science is based. Whether physiology in its most comprehensive sense, as understood by the authors of this work in their title, is a single branch of science which can be thus treated in its unity, or whether it ought to be divided up and incorporated with others already established, is a point which has not yet been satisfactorily settled, and which the perusal of this book may assist in proving.

The work is in two volumes, the first, much the larger, being devoted to the text, while the second contains the drawings of the microscopical preparations described, as well as the instruments, diagrams, and dissections referred to.

The histological section, written by Dr. Klein, is, as a whole, far superior to any existing work on the subject, which is saying a great deal, considering the large number of treatises on the use of the microscope, in the study of the tissues of the animal body, which have already appeared. The careful way in which all the many details receive their due consideration, is an example to authors of text-books, and it is rendered evident on every page that the author is himself thoroughly familiar personally with the points he records. Many methods till now comparatively little known and employed in this country are fully discussed, among the most important of which is that of injecting organs by the "method of puncture," introduced by Ludwig, which though it in many cases gives very decided results, has to be used with caution, as their interpretation is often far from easy and sometimes misleading. The minutest details, the omission of which so often mars the results are given in many cases as well as if the teacher himself were by the side of his pupil. The means to be employed for obtaining a view of the stomata of the lymphatic system, as they are seen on the centrum tendineum of the diaphragm, is a case in point to which several pages are devoted, in which also the structure of these little understood organs is excellently entered into. The chapter on embryology is also very complete; the paragraphs on striated muscular fibre are as logical as they are clear, the following being the summary:—"From all these (the previous) facts we learn that the substance of a muscular fibre consists, in the first place, of oblong prisms, *i.e.*, sarcous elements, with their axes parallel to its axes, and formed of a material which refracts light strongly, is stained strongly with silver, slightly with solution of chloride of gold, and swells out in the fresh state on the addition of water; and secondly, of a less refractive transparent interstitial substance occupying the remainder of the space, which is not coloured by silver, but is intensely stained by chloride of gold, and disappears in dilute acetic acid." The illustrations accompanying the descriptions are new, and on a sufficiently large scale to render quite apparent the minutest structural points; much may be learnt from a simple inspection of them. We do not quite like the introduction of so many German synonyms for many of the terms employed, they convey but little meaning to most English students, and though otherwise harmless, they might be taken to indicate that our language is poor in mechanism, or that we are overpoweringly indebted to our worthy relations, neither of which views is strictly correct. A little consideration might have been shown to our microscope makers by the employment of the well-known English nomenclature of objectives (for a man may be a first-class histologist and yet not know the meaning of Hartnack's No. 10), and the systematic ignoring of their excellent workmanship cannot but produce ill-feeling; for though they may be expensive, they have undoubtedly been the originators of most of the greatest improvements in their branch.

FIG. 1.—Centrum tendineum of rabbit, seen from the abdominal side. Berlin blue had been introduced into the peritoneum by "natural injection." *b*, Straight interfascicular lymphatics between the bundles of tendon of the abdominal side; *a*, lymph vessels of the pleural side, showing the valves, with corresponding dilatations. The last lymph vessels are as completely injected as the first. (Oc., 3: Obj, 4. Tube not drawn out.)

Dr. Sanderson has undertaken the physiology of the blood, together with that of the circulation, respiration, and animal heat. The chapter on the first of these subjects is excellent and thorough, nothing better could be wanted, the author being able to keep within the region of fact. The German elaborate verifications of the supposed functions of many of the most important nerves, are given in a very lucid and concise manner, and several of the excellent instruments introduced by them are clearly described, together with the principles of their action, and the methods of employing them. But in the other more

theoretical subjects, there are many statements to which we must take exception. Most of the theories bearing on some of the main problems in the circulation of the blood, are at the present day in too unsettled a state to find a place in a manual for students, because it is impossible in the permissible space to give the many conflicting results of different authors, which yet remain unproved or unrefuted. The result is, as might be expected, that a one-sided and individual view of the subject is presented, and the student is taught some things which he will have to unlearn. Most of Dr. Sanderson's theories have already appeared, but nevertheless some are based on principles undoubtedly unsound.

Whilst discussing the expansive movements which occur in an artery during the different parts of the pulse beat, and the cause of the variations in the extent of the changes in diameter of the arteries which may be observed, the following occurs :—"A moment's consideration teaches us that there are two circumstances which must diminish the minimum pressure in the arteries, viz., diminution of the mean arterial pressure, and prolongation of the period which intervenes between one expansive act and its successor. In other words, *the less frequent the*

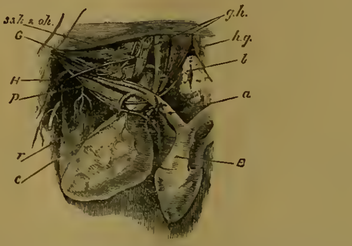

FIG. 2.—Dissection of the parts in relation with the vagus nerve of the frog on the right side. The oesophagus is distended with a glass tube about half-an-inch in width. The object is represented of about twice its actual size *a*, right aorta ; B, *bulbus aortæ* : *c*, posterior horn of the hyoid bone ; *g h*, genio-hyoid muscle ; *h g*, hyo-glossus muscle ; *p*, lowest of the three petrohoid muscles ; H, ninth nerve ; G, glossopharyngeal nerve ; *r*, vagus ; *l*, larynx ; *s* & *h* & *o h*. point to the space occupied by the origins of the large muscle (sternohyoid) which connects the hyoid with the sternum, as well as by the omohyoid ; both of these muscles have been cut away.

contractions of the heart and the lower the arterial pressure, the greater the expansion in proportion to the expanding force which produces it" (the italics are not ours). Dr. Sanderson would undoubtedly thus lead us to believe that this is a self-evident proposition, but that it is so is far from the case. That it should be true it has to be assumed that the escape of blood from the peripheral vessels *between two succeeding pulse beats*, depends on the interval which elapses between them, and no attempt is made to prove this fact, which is not at all necessarily correct, and against which many arguments can be adduced. The same author also adopts a modification of the now antiquated and decidedly insufficient oscillatory hypothesis, to account for the dicrotic beat of the pulse, so clearly seen in the sphygmograph trace: and in so doing he necessarily ignores the great value of the important and very definite results obtained by Chauveau and Lortet, by means of their hæmadromograph ; if he had fully realised the easily demonstrable fact that the second rise in the sphygmograph trace *commences* the later in an artery according as it is farther from the heart, the table on p. 228 referring to the relations of the different elements of the pulse beat in different vessels could not have appeared in its present form. As long as physiologists compare arteries to elastic tubes in air, they must be led into error, for the forces which predominate in them so situated, are very different from those which prevail when they are surrounded by water or any yielding substance, which an artery much more directly resembles, as it is surrounded by, and on most sides in contact with, tissues of a somewhat yielding nature. There is another short sentence we must quote ; in explaining the action of the auriculo-ventricular valve we read : "The time which intervenes between the commencement of the compression and the tightening of the valve varies according to the vigour of the contractions, the quantity of the blood contained in the ventricle, and the previous position of the valve, must always be appreciable." Does the author really wish us to believe that the heart, a powerful muscular pump, which he affirms (though on very slight grounds) acts most powerfully at the commencement of each beat, requires an appreciable time, by which we understand, one that can be measured by instruments at our command, to tighten the auriculo-ventricular valve, against which the resistance is undoubtedly extremely small ? it seems very improbable.

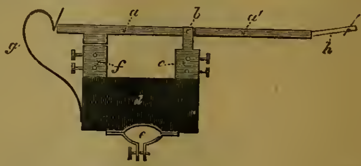

FIG. 3.—The marking lever for indicating graphically on a revolving drum the moment at which an electric current is broken.

The chapter on animal heat contains much useful information, but several of Senator's results are not entered into, and Laschkewitsch's explanation of the fall of temperature in "varnished" rabbits, which are discussed in detail, is not given. None of the special precautions which have to be taken in employing the mercurial thermometer for physiological investigation, are referred to ; and the student will be entirely misled respecting the principle upon which the ordinary clinical thermometer of Phillips is constructed, the author having muddled up with his description Hawksley's method for preventing the index running into the bulb whilst the operator is depressing it, which is entirely independent of, and has nothing to do with, the self-registering power of the instrument. A similar want of knowledge of physics is shown on the same page on which this error occurs, for it is stated that in the thermometric couple the degree of deflection of the galvanometer needle, which is produced when a current results from the unequal heating of its ends, varies with the difference of the temperature of the junctions, which is well known to be incorrect.

Dr. Foster, in undertaking the "Functions of Muscle and Nerve," has undoubtedly had a difficult work to perform, and he has introduced a very clear and simple method of teaching the various, and in many cases, dis-

connected facts which relate to them. The student will, in this section of the work, find full directions for performing most of the experiments, which will, when all repeated, enable him to advance on a thorough and sound foundation. Great care is taken to render evident the phenomena of electrotonus, and the subject of tetanus is dwelt on in detail, the following being the propositions which are discussed and proved regarding it:—1. "Tetanus from an ordinary interrupted current is a continuous contraction rapidly reaching a maximum, continuing (within limits) in that condition so long as the current is passing, and followed by a gradual relaxation upon the current being cut off." 2. "Tetanus really consists of a series of simple muscular contractions fused together." The apparatus necessary for verifying these and other points in which electricity plays a part, is described as far as is necessary for the wants of the physiological student, and some, as Wippe's double key and Du Bois Reymond's rheocord, are figured. Several of the points insisted on appear to be insignificant in themselves, but they must all, in the long run, have important bearings on future theory.

In undertaking the "Physiological Chemistry," Dr. Brunton has had a somewhat easier task than the two authors last referred to, and his work is excellent. The results of Hoppe-Seyler, and other German chemists, which are as convincing as they are connected, are fully entered into, and the chemistry of digestion and excretion, together with the method of arriving at them, are explained at considerable length. As an instance of the manner in which the subject is handled, the following are the propositions which are demonstrated in connection with the fact that pepsin is not destroyed during digestion. 1. "Although the digestive power of pepsin appears to be indefinite, yet a limited quantity of gastric juice will not dissolve an unlimited quantity of fibrin." 2. "The arrest of digestion in this experiment (the proof of the previous proposition) is not due to the destruction of pepsin, but to the accumulation of the products of digestion in the liquid and to the want of acid." 3. "A stronger acid is required for digestion if the products of digestion are present in quantity in the solution." The theory of digestion, together with the action of the vagus and splanchnics on the stomach are fully discussed, and the unassuming way in which the author states his own opinions carries great weight with it.

We should have liked to have seen a separate chapter on the methods to be used for rendering animals insensible, together with a notice of the relative value of different anæsthetics and the way to exhibit them; as it is, the subject is only incidentally mentioned in connection with special operations. If the drawings of the instruments had been incorporated in the text they would have been more easily referred to, and therefore more frequently looked at; as it is, the one volume without the other is difficult to understand. The anatomical sketches, mostly after Bernard, which illustrate the distribution and relations of the nerves and vessels that so frequently have to be manipulated by operating students, adds much to the completeness of the work, in which every effort has evidently been made to put the student in as good a position with regard to the subject as can be desired.

The three accompanying woodcuts are from the second volume of this work. The largest is an example of the size and character of the excellent illustrations in Dr. Klein's histological section. Dr. Sanderson contributes that illustrating the relations of the pneumogastric nerve in the frog, and the third is one of the several electrical instruments described by Dr. Foster.

WILSON'S INORGANIC CHEMISTRY

Inorganic Chemistry. By the late George Wilson, M.D., F.R.S.E. Revised and enlarged by H. G. Madan, M.A. (London and Edinburgh: W. and R. Chambers.)

LIKE so many of our old friends among the best books on chemistry, the present edition of the late Prof. Wilson's Inorganic Chemistry has undergone somewhat extensive alterations, and received considerable additions, which, in the opinion of its able editor, have been rendered necessary by the recent progress of chemistry. The original plan, which is that adopted in some of our best text-books, has been adhered to, viz. of introducing the student to a knowledge of the more important fundamental laws of chemistry, and to make him familiar with the properties of the chief elementary substances, and their more remarkable compounds. What is generally known by the name of chemical physics occupies about one-fourth of the whole book. This portion is clear and concise, and deserves the highest eulogium. It may be perused with advantage by every chemical student. The theory of atomicity of elements, which is fast giving a new impression to organic chemistry, and which by some of our most eminent chemical teachers has of late been introduced into the domain of inorganic chemistry also, and which promises to reconcile and harmonise both branches of chemical science, has received but scanty recognition at the hands of the editor, although he professes to have brought the chemical nomenclature (in deference to the wishes of the publisher), into accordance with the system adopted by Profs. Frankland and Williamson.

Professor Wilson seems to have felt that physical and chemical laws cannot be studied with advantage without having some physical and chemical facts to work upon, and the pupil is therefore recommended to read the first 108 pages, treating of chemical physics, with some care before proceeding further; but "he is not to expect to understand the introductory portion at once, but must go back from time to time to their study, when he will find them more and more intelligible as he grows familiar with the properties of chemical substances," explained in the later pages. Is not this an admission that the plan upon which the book is constructed is a faulty one? Is it not time to relegate chemical physics to physics proper, especially when we have such excellent elementary text-books as Balfour Stewart's and others, and to treat of chemical changes in chemical text-books? Not that we would have it inferred that chemical changes can be understood without a knowledge of the general properties of matter, of heat, light, and electricity. By far the greater number of chemical changes being dependent upon chemical affinity, the laws of chemical combining proportions and volume composition can very well be explained by confining the teaching at first mainly to chemical changes. Physical considerations, especially at

a time when they undergo such rapid extensions, should form the crowning part of chemical studies, and the interdependence of the two branches of science can only be established upon a sound basis when a thorough knowledge of either science has been acquired.

The main portion of the book comprising the chemistry of the non-metallic and metallic elements, arranged under the usual headings Preparation and Properties of the different elements and their compounds, contains much that will highly recommend itself. The more important compounds are dealt with in a manner which will help the student over most of the difficulties he encounters at first, and will enable him to lay a good foundation for more extensive chemical studies. The classification of the metals according to their atomicity—open to objections as it stands—is not always reconcilable with the analytical summaries or tests given after each group of metals, nor are the analytical explanations always accurate. On p. 393, *e.g.* we notice: "Calcic sulphate cannot produce a precipitate in a salt of calcium, because there is more than enough of water present to retain dissolved all the sulphate that can possibly be formed."

There can be little doubt that the new edition of Wilson's Chemistry will be welcomed by all who desire to get a general insight into the science, and that it may be studied with advantage in preference to many larger and more ambitious text-books.

OUR BOOK SHELF

Verhandlungen der k. k. geologischen Reichsanstalt. Nos. 11 to 18. (Vienna.)

THESE numbers of the Proceedings of the Geological Society contain many useful papers, chiefly, however, of local interest. Felix Karrer notes the occurrence of mammoth remains at Vienna. They were obtained during the sinking of a well in a "diluvial" (glacial) deposit at a depth of 9 fath. 3 ft. from the surface. Dr. Lenz also has a short reference to a similar discovery of the teeth of a young mammoth in a brown laminated loam near Nowakmühle. Dr. Stur gives an interesting account of his own and Baron Petrino's observations on the superficial deposits in the basin of the Dniester in Galicia and Bukowina. A great accumulation of loess covers a wide area in that district, the land shells and mammalian remains in which enable these geologists to correlate it with the loess of the Rhine and other regions. We observe, in No. 11, an important table showing Dr. C. E. Weis's systematic arrangement of the carboniferous formation and the rothliegendes formation of the Saar-Rhine district, which is well worth the attention of English geologists. The usual admirable literary notices, and other miscellaneous matter, are appended to each number of the Proceedings.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Leaf-Arrangement

THE chief part of the Rev. G. Henslow's objections (NATURE, vol. vii., p. 403) to my condensation-theory of leaf-arrangement are due to a double oversight on his part. First, he has overlooked the condition of *contact* among the balls which I use to represent embryo leaves. Second, he has overlooked the fundamental position, that leaf-order exists for, and is determined in, the *bud.*

The bud requires economy of space. This involves contact among the embryo leaves; and if we experiment with balls attached (as described in my paper) in two rows alternately on either side of a contractile axis, we shall see that when the axis is allowed to contract with a twist, that twist is necessarily limited by the conditions of contact which arise, and that we cannot "cause it to make a complete rotation if we choose." Given the size of the balls and their distance from the axis, the position which they will assume (under contraction with a twist) is necessarily determined by the geometrical conditions of mutual contact. This consideration furnishes the answer to Mr. Henslow's italicised query, and also to his two previous questions (1) and (2). It also gives back a "really explanatory meaning" to my expression "*maxima* of stability," for if we have one sphere standing almost vertically on another and supported by a third and a fourth to right and left, we have therein some statical conditions which admit of maxima and minima of stability. The same consideration also removes the objection that "the positions taken up by the balls must be arbitrary, or at least in proportion to the twist given by the hand—a perfectly arbitrary force." The twist given by the hand in my experiment serves only to determine the direction of the real twist; the subsequent real availing twist is insisted upon by the two ranks of balls-in-contact as the sole condition of obedience to the contractile force of the indiarubber axis; and this twist is limited by the conditions of contact above described. Let the direction of the twist be given, and there is nothing arbitrary in the result.

The objection that "if an axis becomes twisted the *fibres* will be twisted also" loses force if we bear in mind that the leaf-order is imposed upon the embryo leaves in the very earliest stage of their bud-life; and that the formation of fibres, taking place at a subsequent stage, must find itself compromised by an already existing arrangement of the embryo leaves. The elastic band in my experiment, "if it were a pliant shoot," would certainly "contort the vessels and wood-fibres;" but it was not meant to represent a "pliant shoot" except in its earliest embryonic bud-stage, and that at some very remote period in the past.

I must ask Mr. Henslow to bear in mind that he has before him only the abstract of my paper, and that necessary brevity has left some points too bare, and has wholly suppressed others of small importance. Among the latter is some mention of the "secondary series" $\frac{1}{3}$, $\frac{1}{4}$, $\frac{2}{7}$, &c., which, though it may be found in the abnormal variations exhibited by a cultivated plant like the Jerusalem Artichoke, yet cannot be reckoned with examples of normal leaf-order.

Let me take this opportunity of insisting again on the astonishing agreement between the facts of nature and the results which the condensation-theory leads us to expect. Taking one member to start from as 0, we find in nature that the members in contact with 0 belong to the following series, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, &c., and these are the very same members which would necessarily be brought into contact with 0 under successive degrees of condensation with twist from an original order $\frac{1}{2}$.

I have lately met with a striking confirmation of the truth of the condensation-theory. The simplest order of the whorled type is that in which the leaves stand in pairs, decussate. Now if we consider what would be the result of condensation with twist applied to this arrangement, we can see that it would produce a new series of orders, in which the following members would successively come into contact with 0,—2, 4, 6, 10, 16, 26, 42, &c., and would present the phenomenon of 2, 4, 6, 10, &c., spirals alternately to right and left. This result is exemplified in nature. The teazle (*Dipsacus silvestris*) has the decussate order in its leaves; and in its head (where we might expect to find its leaf-order condensed) we count sixteen conspicuous spirals in one direction and twenty-six in the other:—that is to say, we have 0 in contact with No. 16 on one side and No. 26 on the other. No. 42 stands higher between 16 and 26, but inclined towards the former. No. 10 stands next below 26, and No. 6 next below 16. These numbers belong to the new series above mentioned.

This close parallel between fact and theory appears to me to give a value to the latter which it will not lightly lose.

The Hegelian Calculus

As Dr. J. H. Stirling has enjoyed the exceptional privilege of replying contemporaneously to my paper on Hegel in the

current number of the *Fortnightly*, I should desire, with your kind permission, to find in your columns the opportunity of saying without delay the single word which still seems necessary between Dr. Stirling and myself.

Dr. Stirling now holds that the real question between him and me is whether or not Hegel "attempted" to produce "a Hegelian Calculus." And so it seems to him a virtual concession of the entire case when I say that the phrase "Hegelian Calculus" is used by me in irony. Dr. Stirling, I fear, misunderstands me. What Hegel has given us on the subject of the Calculus is, strictly speaking, nonsense. But, as I have shown, this nonsense is not mere metaphysic, but involves mathematical absurdity. It is of course only in irony that one can dignify the paradoxes of mathematical ignorance with the title of a Calculus; and if this admission satisfies Dr. Stirling, then our controversy is at an end. W. ROBERTSON SMITH

Aberdeen, April 3

Meteorology of the Future

I WISH to call the attention of the writer of the article "The Meteorology of the Future," which appeared in NATURE of December 12, 1872, to a little work which appears to have entirely escaped his notice.

In the beginning of 1871 I circulated a small book of twenty-four pages, containing results deduced from the observations made at this Observatory, 1841 to 1870. I have given the decimal and annual variations of all the meteorological elements collected, and have pointed out their mutual interdependence. I have also given on an enlarged scale the curves of variations of annual mean temperature and freedom of the sun's disc from spots, which appeared in the Proceedings of the Royal Society, March 23, 1871.

No one acquainted with the subject would, I presume, believe that periodical variations could exist in the temperature without existing also in the other meteorological elements; vapour as measured by tension, hence barometer humidity and rainfall.

In the introduction to the work referred to, it is stated with regard to the curve of temperature and inverse curve of solar spots:—"There is an agreement between the curves which will probably be regarded as too close to be the result of accident, and which renders it probable that the two phenomena, represented by the curves, result from the action of a common cause connected with changes of mean solar energy." And this established with more or less probability, I proceeded to point out (p. 17)—"That the variations of temperature are borne out by those of tension of vapour," and on page 22—"That the correspondence between humidity and rainfall is strongly marked," and also that—"The correspondence between a curve swept to represent the variations in rainfall and the inverse curve of the variations in mean temperature is of a marked character."

You will perceive, therefore, that the connection between solar spots as an indication of less solar heating power and vapour, and rain, as well as temperature, was in the book referred to explicitly pointed out. I may add to this note, that the rainfall for

1871 was 20·098 inches
1872 was 29·325 inches.

Royal Observatory, Cape of Good Hope

Bright Meteor

I HAVE this evening, at 7.40, seen the brightest meteor I have ever beheld: starting from a point about half-way between Cassiopæa and the Pole star, it descended through about 20° of arc, when it was lost sight of behind a cloud: this cloud was a thick white opaque cloud shining brightly in the moonlight, but the meteor behind it illuminated the sky, and made the cloud appear for the moment dark against it.

The colour of the meteor was a decided green; its passage was not very rapid; it appeared far brighter than any star or planet, and seemed to have a short tail. Not only was it a gloriously beautiful object in itself, but it illuminated all the sky in its neighbourhood with its greenish light.

EDMUND H. VERNEY, Commander R.N.

H.M.S. *Growler*, off Cape Matapan, March 5

The Great Meteoric Shower of November 27, 1872

THIS interesting display was also observed in the neighbourhood of the small town of Santa Lucia in Venezuela (10° 12′ N., 68° 57′ W. from Paris), by Dr. A. Alamo. The first meteors were seen at half-past 7, about 100 in 30 minutes. Most of them followed an easterly course, some leaving a luminous track visible for several minutes. From 8 to 12 o'clock their number was too large for counting, but after midnight the weather got misty, and few meteors could be distinguished. The shower, however, continued, and still in the morning some meteors were traceable. Unfortunately Dr. Alamo cannot say anything about the radiant point of the shower. At Carácas the sky was densely overcast, and not even a glimpse of the spectacle could be obtained. DR. A. ERNST

Carácas, Feb. 21

The Antiquity of Man

THE letter of Sir John Lubbock in your issue of March 27, induces me to call attention to what seems to me to be an anomaly in the state of our evidence concerning fossil man. Sir J. Lubbock has insisted, and with much reason, on the parallelism between the condition of existing savage races and that of fossil man; but, I would ask, is there any existing savage race capable of delineating animals in the masterly way in which the elephant is delineated on the plate of bone figured at page 326 of NATURE (February 27, 1873)? Such a life-like representation as is here produced by a few rough scratches would not discredit a modern artist. Unless I am under a misapprehension, the best figures that living savages can produce are but uncouth things, in which case either the parallelism between the intelligence of existing savage races and of fossil man fails in one important particular, or else a suspicion arises as to the contemporaneity of these engraved bones with palæolithic man; and a doubt is thrown on the supposed antiquity of the Troglodytes to whose hands this engraving is ascribed.

We should, I think, until this discrepancy is explained, look with still greater suspicion upon the contemporaneity of engraved representations of animals with so early a form as Miocene man, or accept them as any evidence of his existence at that epoch.

While suggesting the above caution, I would not, however, be understood to dissent from the probability of some form of man having existed as far back as the Miocene period, since, eleven years ago, I observed in the *Phil. Mag.* (for April, 1862, last paragraph but one of the paper) that the views there discussed "seemed to me to lead us to the presumption of a far greater antiquity for our race than had hitherto been accorded to it, reaching perhaps far back into the Tertiary period."

Brentwood, Essex SEARLES V. WOOD, JUN.

Skeletons at Mentone

A VERY accomplished geologist, a friend of mine, is now staying at Mentone, for the benefit of his health, and he writes to me under the date of the 25th ult. as follows:

"Another skeleton has just been found here in one of the caverns. It is far less perfect than the former one. The head is crushed and partly wanting, and a considerable portion of the vertebral column is absent. The limbs, however, indicate a person of larger size than the first skeleton. On the arms are bracelets of shells, which are bored for stringing. The parts found are lying in their natural position. With the skeleton are traces of what looks like very fine iron ore. Of this substance there is but a very small quantity, perhaps two or three table-spoonfuls."

With regard to the iron ore, there have been many conjectures, and it is extremely remarkable that about the same quantity of a similar substance was found with the first skeleton. The more general opinion seems to be, that this material was employed in some burial rite. W. T.

Torquay, April 1

[From a cutting from *Les Echos de Cannes* sent us by W. T., we learn further that the head was covered by a network of shells, and that beside the skeleton were found many implements of bone, and even drawings of fish and swans.—ED.]

Instinct

Perception in Ants

THE following fact with respect to the habits of ants, which I believe to be quite new, has been sent to me by a distinguished geologist, Mr. J. D. Hague; and it appears well worth publishing. CHARLES DARWIN

On the mantelshelf of our sitting-room my wife has the habit of keeping fresh flowers. A vase stands at each end, and near the middle a small tumbler, usually filled with violets.

Sometime ago I noticed a file of very small red ants on the wall above the left-band vase, passing upward and downward between the mantelshelf and a small hole near the ceiling, at a point where a picture-nail had been driven. The ants, when first observed, were not very numerous, but gradually increased in number, until on some days the little creatures formed an almost unbroken procession, issuing from the hole at the nail, descending the wall, climbing the vase directly below the nail, satisfying their desire for water or perfume, and then returning. The other vase and tumbler were not visited at that time.

As I was just then recovering from a long illness it happened that I was confined to the house, and spent my days in the room where the operations of these insects attracted my attention.

Their presence caused me some annoyance, but I knew of no effective means of getting rid of them. For several days in succession I frequently brushed the ants in great numbers from the wall down to the floor; but as they were not killed the result was that they soon formed a colony in the wall at the base of the mantel, ascending thence to the shelf, so that before long the vase was attacked from above and below.

One day I observed a number of ants, perhaps thirty or forty, on the shelf at the foot of the vase. Thinking to kill them I struck them lightly with the end of my finger, killing some and disabling the rest. The effect of this was immediate and unexpected. As soon as those ants that were approaching arrived near to where their fellows lay dead and suffering, they turned and fled with all possible haste. In half an hour the wall above the mantelshelf was cleared of ants.

During the space of an hour or two the colony from below continued to ascend, until reaching the lower beveled edge of the shelf, at which point the more timid individuals, although unable to see the vase, somehow became aware of trouble and turned about without further investigation; while the more daring advanced hesitatingly just to the upper edge of the shelf, where, extending their antennæ and stretching their necks, they seemed to peep cautiously over the edge until beholding their suffering companions, when they too turned and followed the others, expressing by their behaviour great excitement and terror. An hour or two later the path or trail leading from the lower colony to the vase was almost entirely free from ants.

I killed one or two ants on their path, striking them with my finger, but leaving no visible trace. The effect of this was that as soon as an ant ascending towards the shelf, reached the spot where one had been killed, it gave signs immediately of great disturbance, and returned directly at the highest speed possible.

A curious and invariable feature of their behaviour was that when such an ant, returning in fright, met another approaching, the two would always communicate, but each would pursue its own way; the second ant continuing its journey to the spot where the first had turned about and then following that example.

For several days after this there were no ants visible on the wall, either above or below the shelf. Then a few ants from the lower colony began to re-appear, but instead of visiting the vase which had been the scene of the disaster, they avoided it altogether, and following the lower front edge of the shelf to the tumbler standing near the middle, made their attack upon that. I repeated the same experiment here with precisely the same result. Killing or maiming a few of the ants and leaving their bodies about the base of the tumbler, the others on approaching, and even before arriving at the upper surface of the shelf where their mutilated companions were visible, gave signs of intense emotion, some running away immediately and others advancing to where they could survey the field, and then hastening away precipitately.

Occasionally an ant would advance towards the tumbler until it found itself among the dead and dying, then it seemed to lose all self-possession, running hither and thither, making wide circuits about the scene of the trouble, stopping at times and elevating the antennæ with a movement suggestive of wringing them in despair, and finally taking flight.

After this another interval of several days passed during which no ants appeared. Now, three months later, the lower colony has been entirely abandoned. Occasionally however, especially when fresh and fragrant violets have been placed on the shelf, a few "prospectors" descend from the upper nail hole, rarely, almost never, approaching the vase from which they were first driven away, but seeking to satisfy their desire at the tumbler. To turn back these stragglers and keep them out of sight for a number of days, sometimes for a fortnight, it is sufficient to kill one or two ants on the trail which they follow descending the wall. This I have recently done as high up as I can reach—three or four feet above the mantel. The moment this spot is reached an ant turns abruptly and makes for home; and in a little while there is not an ant visible on the wall.

JAMES D. HAGUE

San Francisco, California, Feb. 26, 1873

Perception in Butterflies

THE interesting discussion on this subject in your columns has hitherto been almost entirely confined to facts of extraordinary "perception" with mammalia. But in other classes of the animal kingdom there occur instances perhaps even more astonishing still, showing a power of perception which we needs must attribute to smell, unless we are inclined to talk about natural forces hitherto unknown, to which I should prefer saying that we do not yet understand the matter at all.

In the valuable monthly, "Der Zoologische Garten," v. X. (1869) p. 254, there is a paper on the sense of smell in butterflies, recording, among other cases, the following one.

A well-known collector, the late M. Riese of Frankfort, bred a crippled female of *Lasiocampa pruni*, a species very rare here. M. Riese dwelt in a narrow and densely-peopled lane near the centre of this city. He put the said moth before the window with his other boxes, and soon had the pleasure to find it surrounded by some males, which became the collector's welcome prey. Here, as the writer fitly remarks, the performance of the male in finding out the female was the more surprising, by the latter being confined in the middle of the town as well as by the rarity of the species in general.

If, as the writer adds, there can be any doubt of the males being guided in these cases by smell, what is more to be wondered at, the acuteness of the males (supposed to be located in the large comb-shaped antennæ) or the enormous divisibility of the odour emitted by the females?

I may add that similar and even more striking cases (the females being confined within a room, and the males appearing outside at the windows) have been recorded by that most reliable observer, the late Dr. von Heyden.

Though I am not prepared to follow the whole length of Mr. Darwin's ideas on "Pangenesis," yet I cannot avoid observing how much such facts as these seem to support the fundamental assumption of that "provisional hypothesis," namely that organised matter is capable of a degree of divisibility scarcely conceivable by us, yet retaining in those most minute particles, infinitely smaller than any which can be revealed by our microscopes, all its specific distinctness,—the "gemmulæ" issuing from the female of a particular species reaching and affecting the distant male, and thereby testing their particular, specific nature.

J. D. WETTERHAN

Frankfort-on-the-Maine, April 5

Perception in Fowls

SEEING in NATURE many letters on the instinct of animals I am tempted to send you an incident which fell under my notice and which would seem to denote in domestic fowls a greater amount of reasoning power and of intercommunication than the lower animals are usually credited with.

Three years ago I was staying at a house in Ireland where a good deal of poultry was kept, and a young white duck just feathered being the only one left of a brood was allowed to roost with a hen and a young brood of chickens under the furnace in the back kitchen, to keep it from the rats which infested the out-houses. One evening our attention was called by the servants to a great commotion between the hen and the duck, which had always before been excellent friends, and upon close examination it was discovered that the duck was not the hen's usual companion, but although closely resembling it in age and colour, was a perfect stranger, not even belonging to the premises at all, whilst the proper duck was found quietly resting with the other ducks in the duck-house. The intruder having been ejected, and the ordinary bed-fellow restored to the hen, peace again reigned between the feathered companions; but the singular part of the affair is, how the duck could have

met with a stranger so nearly like herself, and induced it to take her own nightly place in a strange house and with a strange hen.—Was it an act of charity towards a stranger wandering in search of a night's lodging? or was the duckling tired of the hen's company, and desirous of joining the birds of her own feather, and so cajoled the stranger so nearly resembling herself to take her place, believing the cheat would not be discovered?

I commend this fact, for which I can vouch, to Mr. Darwin.

Bath, March 31

Acquired Habits in Plants

ON Oct. 24 last, I found by the banks of the little river Aled, in North Wales, a dog-violet, which, in the first place, was in flower at that unusual season, and in the second place, growing in a hedge, had assumed the habit of a climbing plant. Its stem measured 2½ feet in length; it bore sixteen alternate leaves, the flowers being axillary, or rather some axils had flowers in them, and others had branches of leaves with flowers axillary in these. One flower only was actually in bloom, but there were several (five or six) seed vessels. I gathered one plant and have it still.

St. Asaph, N. Wales J. G.

SCIENCE AND THE PRESS IN AMERICA

(FROM A NEW YORK CORRESPONDENT)

THE visit of Prof. Tyndall has given an extraordinary impulse to scientific affairs in this country. It took place at a fortunate moment, just after the heat and turmoil of a presidential election had been transformed into the national sorrow over the death of the defeated candidate; just before the exposures of corruption, which have since disgraced eminent public men, had begun to absorb popular attention. It therefore happened not only that men's minds were not preoccupied, but that, in addition, newspaper columns were not specially crowded. Hence all the leading newspapers gave more space than would have otherwise been possible, to reports of Prof. Tyndall's lectures. In this particular, however, one paper surpassed the rest, giving the lectures verbatim and with illustrations, and afterwards reprinting them in a separate sheet, which, as you are probably already informed, attained a special circulation outside that of the newspaper, of more than 200,000 copies. It is not improbable that this enterprise on the part of the *New York Tribune* originated in a programme for the management of that paper laid down by the late Mr. Greeley. This was printed in its columns the second day after the election, when he resumed his position as editor of the paper. The card specified among other things, first, that thereafter the paper would be enabled to give "a wider and steadier regard to the progress of science, industry, and the useful arts." His successors in the management of the paper have been anxious, for obvious reasons, that it should tread the path he had marked out for it; Tyndall's coming furnished the first opportunity. Other papers have been stimulated by the popularity of scientific topics which the success of these lectures revealed, and there never was a time when such themes found such general acceptance with the newspaper press.

The first manifest benefit to science which has resulted, is an improvement in the treatment of scientific subjects, so far as they are editorially considered. It is not a year since one of the New York newspapers contained an article upon a proposition to light streets and houses by means of hydrogen and oxygen conveyed in separate systems of pipes. In that article there was displayed an ignorance of the commonest facts of chemistry that seemed almost incredible. It teemed with the most ludicrous absurdities. But even its rivals never perceived the blunders—they had a fair share of their own, for the most part, whenever they handled such topics. But of late the writers in the New York newspapers have exhibited some knowledge ot such subjects; at all events, special articles in some of the papers betray the touches of a professional hand, that come not with the surface knowledge of journalism.

The second evident benefit has to-day a signal illustration. The efforts of Prof. Tyndall were particularly directed toward impressing upon those of our citizens who have the means for such aid, the benefit that results to the community from the promotion of scientific inquiry This has been also a favourite theme with Prof. Agassiz. A few days ago a Boston correspondent of the *New York Tribune* sent a description to that paper of the work that Prof. Agassiz had undertaken at the Museum of Comparative Zoology; his efforts to obtain State assistance from the Massachusetts legislature; his needs and difficulties, and unsparing, disinterested industry; his project for founding a school of natural history on the coast of Nantucket, where practical work with the dredge might enable the students to become acquainted with marine organisms in a condition of nature. The newspaper commented on the correspondence, pointing out the value of such services, of such researches. The letter and comment interested Mr. John Anderson of this city—a gentleman who has gained wealth as a tobacco manufacturer. Some years ago, finding his health suffering from too close application to business, he selected as a salubrious retreat an island on the New England coast. It is one of the Elizabeth Islands, between Vineyard Sound and Buzzard's Bay. You will best know just where this is, by the fact that New Bedford, the old whaling port of Massachusetts, is on Buzzard's Bay. He expended about 25,000 dols. in improving Penikese Island, and in its delicious climate he regained his health. He refused 75,000 dols. for the island, valuing it at 100,000 dols. Last week, after reading about the aims and efforts of Prof. Agassiz, Mr. Anderson wrote to him, offering him Penikese Island as a gift, and saying to him that he could there establish his Marine Naturalist's School.

To be a little more specific—as such a munificent gift deserves: Penikese is the most northerly of the three western islands of the Elizabeth group. It is of great fertility; it contains a good summer residence; looks out upon a beautiful bay, where there is good anchorage; has a stone dock, and springs of good water. Here is everything that Prof. Agassiz wanted for his semi-nautical enterprise.—Stay! not everything. When Prof. Agassiz first recovered from his surprise, and was thanking the donor, he mentioned a little embarrassment. He had made his arrangements for Nantucket, and there was a little money expenditure involved in the change. "Let not that trouble you" writes Mr. Anderson, and straightway proffers a money-gift in addition—50,000 dols. in cash, "as a nucleus for a permanent endowment fund." And Prof. Agassiz, his heart as well as his coffers running over, says that now his enterprise shall not be merely a summer school, but an institution for all seasons and all time.

The correspondence between Mr. Anderson and Prof. Agassiz will, I am told, be furnished to the press within a few days; but Mr. Anderson is modest; and does not want much fuss about it. It is his first approach toward the hill of science, and he had no personal acquaintance with Agassiz whatever. The scientific sensation of to-day's newspapers is a story that the Natural Bridge of Virginia is burning up. It is told with great detail by eye-witnesses who testify to volcanic burnings and a sulphurous smell, to falling rocks and general danger. Prof. Campbell, of the geological department of the Washington and Lee University, evidently credits the story, and attributes the phenomenon to chemical action, induced by high water acting upon sulphurous and bituminous deposits containing metallic oxides. A New York paper denies the whole story, asserting that the fire proceeds from tar-barrels, and that the whole display is in the interest of hotel-keepers anxious to excite curiosity and attract custom.

ON THE ORIGIN AND METAMORPHOSES OF INSECTS

I.

THE CLASSIFICATION OF INSECTS

NOT many years ago the civil and ecclesiastical authorities of St. Fernando in Chili arrested a certain M. Renous on a charge of witchcraft, because he kept some caterpillars which turned into butterflies.* Most persons, however, are aware that the great majority of insects quit the egg in a state very different from that which they ultimately assume; and the general statement in works on entomology has been that the life of an insect may be divided into four periods. Thus, according to Kirby and Spence * "The states through which insects pass are four: the *egg*, the *larva*, the *pupa*, and the *imago*."

Burmeister,† again, says that, excluding certain very rare anomalies, "we may observe four distinct periods of existence in every insect, namely, those of the egg, the larva, the pupa, and the imago, or perfect insect." In fact, however, the various groups of insects differ very much from one another in the metamorphoses they pass through; in some, as in the grasshopper for instance, the changes consist principally in a gradual increase of size, and in the acquisition of wings; while others, as for

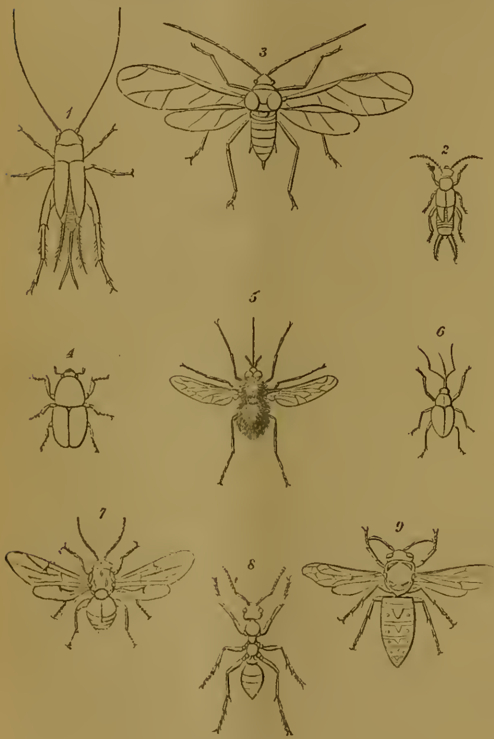

PLATE 1

PLATE 2

PL. 2.—FIG. 1, Larva of Cricket. 2, Larva of Aphis. 3, Larva of Earwig. 4, Larva of Scolytus. 5, Larva of Anthrax. 6, Larva of Balaninus. 7, Larva of Cynips. 8, Larva of Ant. 9, Larva of Wasp.

instance the common fly, acquire their full bulk in a form very different from that which they ultimately assume, and pass through a period of inaction in which not only is the whole form of the body altered, not only are legs and wings acquired, but even the internal organs themselves, are almost entirely distintegrated and reformed. It will be my object to bring these changes clearly before you, and if possible to throw some light on the causes to which they are due, and on the indications they afford of the stages through which insects have been evolved.

The following list gives the orders or principal groups into which insects may be divided. I will not indeed, as this is not a work on the classification of insects, enter into my own views, but have adopted the system given by Mr. Westwood in his excellent "Introduction to the modern Classification of Insects," from which also, as a standard authority, most of the figures on Plates

* Darwin's "Researches into the Geology and Natural History of the Countries visited by H.M.S. *Beagle*," p. 326.

* Introduction to Entomology vi. p. 50.

† Manual of Entomology, p. 30.

‡ When not otherwise acknowledged, the figures on the first four plates are principally borrowed from Mr. Whetwood's excellent "Introduction to the Modern Classification of Insects."

1 to 4, when not otherwise acknowledged, have been taken. He divides the insects into thirteen groups, with reference to eight of which it may be said that there is little difference of opinion among entomologists. These orders are by far the most numerous, and I have placed them in capital letters. With reference to the other five there is still much difference of opinion. It must also be observed that Prof. Westwood omits the parasitic Anoplura, as well as the Thysanura and Collembola.

Orders of Insects according to Westwood.

1.	HYMENOPTERA	Bees, Wasps, Ants, &c.
2.	Strepsiptera	Stylops, Zenos, &c.
3.	COLEOPTERA	Beetles.
4.	Euplexoptera	Earwigs.
5.	ORTHOPTERA	Grasshoppers, Crickets, Cockroaches, &c.
6.	Thysanoptera.	Thrips.
7.	NEUROPTERA	Ephemeras, &c.
8.	Trichoptera	Phryganea.
9.	DIPTERA	Flies and Gnats.
10.	Aphaniptera	Fleas.
11.	HETEROPTERA	Bugs.
12.	HOMOPTERA	Aphis, Coccus, &c.
13.	LEPIDOPTERA	Butterflies and moths.

Of these thirteen orders, the eight which I have placed in capital letters, namely the first, third, fifth, seventh, ninth, eleventh, twelfth, and thirteenth, are much the most important in the number and variety of species. The other five are comparatively small groups. The Strepsiptera are minute insects, parasitic on Hymenoptera. Rossi, by whom they were discovered, regarded them as Hymenopterous; Lamarck placed them among the Diptera; by others they have been considered to be most closely allied to the Coleoptera, but they are now generally treated as an independent order.

The Euplexoptera or Earwigs are only too familiar to most of us. Linnæus classed them among the Coleoptera, from which, however, they differ in their transformations. Fabricius, Olivier, and Latreille regarded them as Orthoptera, but Dr. Leach, on account of the structure of their wings, considered them as forming the type of a distinct order, in which view he has been followed by Westwood, Kirby, and many other entomologists.

The Thysanoptera, constituted of the Linnæan genus Thrips, minute insects well known to gardeners, differ from the Coleoptera in the nature of their metamorphoses, in which they resemble the Orthoptera and Hemiptera. The structure of the wings and mouthparts, however, are considered to exclude them from these two orders.

The Trichoptera, or Caddis worms, offer many points of resemblance to the Neuroptera, while in others they approach more nearly to the Lepidoptera. According to Westwood, the genus Phryganea "forms the connecting link between the Neuroptera and Lepidoptera."

The last of these small aberrant orders is that of the Aphaniptera, constituted of the family Pulicidæ. In their transformations, as in many other respects, they closely resemble the Diptera. Strauss Durckheim indeed said that "*la puce est un diptère sans ailes.*" Westwood, however, regards it as constituting a separate order.

As indicated by the names of these orders, the structure of the wings affords extremely natural and convenient characters, by which the various groups may be distinguished from one another. The mouth-parts also are very important; and, regarded from this point of view, the Insecta may be divided into two series—the Mandibulata and Haustellata, or mandibulate and suctorial groups, between which, as I have already shown,* the Collembola (Podura, Smynthurus, &c.), occupy an intermediate position. These two series would stand as follows:—

* Linnæan Journal, vol. xi.

Mandibulata	*Haustellata*
Hymenoptera	Lepidoptera
Strepsiptera	Diptera
Coleoptera	Aphaniptera
Euplexoptera	Hemiptera
Orthoptera	Homoptera
Trichoptera ?	
Thysanoptera ?	

Again, and this is the most important from my present point of view, insects have sometimes been divided into two other series, according to the nature of the metamorphoses: Heteromorpha, to use the terminology of Prof.

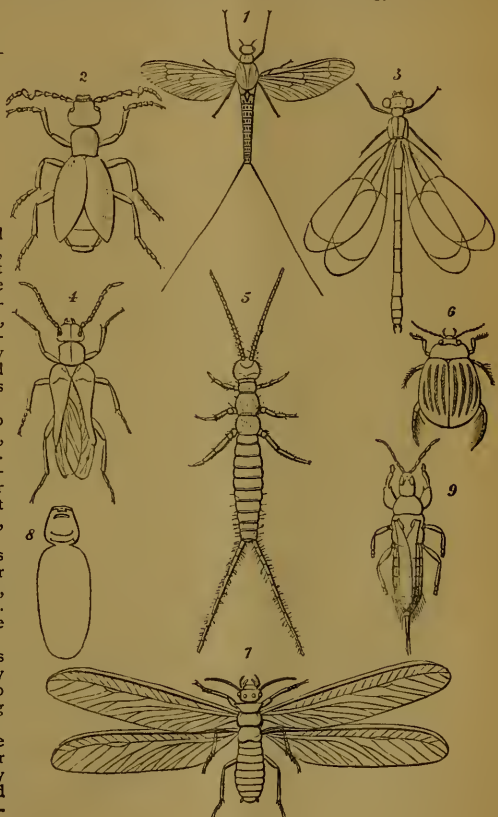

PLATE 3

PL. 3.—FIG. 1, Chloeon. 2, Meloe (after Shuckard). 3, Calepteryx 4. Sitaris (after Shuckard). 5, Campodea (after Gervais). 6, Acilius 7, Termes. 8, Stylops (female). 9, Thrips.

Westwood,* "or those in which there is no resemblance between the parent and the offspring and Homomorpha, or those in which the larva resembles the imago, except in the absence of wings. In the former the larva is generally worm-like and articulated in its form, of a soft and fleshy consistence, and furnished with a mouth, and often with six short legs attached in pairs to the three segments

* Introduction to the modern Classification of Insects, p. 17.

succeeding the head. In the latter, including the Orthoptera, Hemiptera, Homoptera, and certain Neuroptera, the body, legs, and antennæ are nearly similar in their form to those of the perfect insect, but the wings are wanting."

Heteromorpha	*Homomorpha*
Hymenoptera	Euplexoptera
Strepsiptera	Orthoptera
Coleoptera	Hemiptera
Trichoptera	Homoptera
Diptera	Thysanoptera
Aphaniptera	
Lepidoptera	
Neuroptera	

But though the Homomorphic insects do not pass through such striking changes of form as those belonging to the other series, and are active throughout life, still it was until within the last few years generally (though erroneously) considered that in them, as in the Heteromorpha, the life fell into four distinct periods; those of (1) the egg, (2) the larva characterised by the absence of wings, (3) the pupa with imperfect wings, and (4) the imago or perfect insect.

I have, however, elsewhere * shown that there are not, as a matter of fact, four well-marked stages, and four only, but that in many cases the process is much more gradual.

The Hymenoptera are among the most interesting of insects. To this order belong the gallflies, the sawflies, the ichneumons, and above all, the ants and bees. We are accustomed to class the Anthropoid apes next to man in the scale of creation, but if we are to judge animals by their works, the chimpanzee and the gorilla must certainly give place to the bee and to the ant. The larvæ of the sawflies, which live on leaves, and of the Sirecidæ or long-tailed wasps, which feed on wood, are very much like caterpillars, having three pairs of legs, and in the former case abdominal prolegs as well; but in the great majority of Hymenoptera the larvæ are legless, fleshy grubs (Plate 2, Figs. 7-9); and the various modes by which the females provide for or secure them a sufficient supply of appropriate nourishment, constitutes one of the most interesting pages of Natural History.

The pupæ are inactive, and show distinctly all the limbs of the perfect insect, encased in distinct sheaths, and folded on the breast.

In the perfect state these insects are highly organised and very active. The working ants and some few species are wingless, but the great majority have four strong membranous wings, a character distinguishing them at once from the true flies, which have only one pair of wings. The species of Hymenoptera are very numerous; in this country alone there are about 3,000 kinds, most of which are very small.

The sawflies are so called because they possess at the end of the body a curious organ, corresponding to the sting of a wasp, but which is in the form of a fine-toothed saw. With this instrument the female sawfly cuts a slit in the stem or leaf of a plant, into which she introduces her egg.

The larva much resembles a caterpillar, both in form and habits. To this group belongs the nigger, or black caterpillar of the turnip, which is often in sufficient numbers to do much mischief. Some species of this group make galls, but the greater number of galls are formed by insects of another family, the Cynipidæ (Plate 1, Fig. 7). In this family the female is provided with an organ corresponding to the saw of the sawfly, but resembling a needle. With this she stings or punctures the surface of leaves, buds, stalks, or even roots of various plants. In the wound thus produced she lays one or more eggs. The effects of this proceeding, and particularly of the irritating fluid which she injects into the wound, is to produce a tumour or gall, within which the egg hatches, and on which the larva, a thick fleshy grub, (Plate 2, Fig. 7) feeds. In some species each gall contains a single larva; in others, several live together. The oak supports several kinds of gallflies; one forms the well-known oakapple, one forms a small swelling on the leaf resembling a currant, another produces a gall somewhat resembling an acorn, another attacks the root; the species making those bullet-like galls, which are now so common, has only existed for a few years in this country; the beautiful little spangles so common in autumn on the under side of oak-leaves are the work of another species, the *Cynips longipennis*. When the larva is full grown, it eats through the gall, falls to the earth, and turns into a chrysalis. One curious point about this group is, that in some of the commonest species the females alone are known, no one yet having ever succeeded in finding a male.

Another great group of the Hymenoptera is that of the ichneumons; the females lay their eggs either in or on other insects, within the bodies of which the larvæ live. They are thick, fleshy, legless grubs, and feed on the fatty tissues of their hosts, but do not attack the vital organs. When full grown, they eat their way through the skin of the insect, and turn into chrysalides. Almost every kind of insect is subject to the attacks of these horrid little creatures, which, however, are no doubt useful in preventing the too great multiplication of insects, and especially of caterpillars. Some species are so minute that they even lay their eggs within those of other insects. The larvæ of these genera assume very curious forms.

But of all Hymenoptera, the group containing the ant, the bee, and the wasp is the most interesting. This is especially the case with the social species, though the solitary ones also are extremely remarkable. The solitary bee or wasp, for instance, forms a cell generally in the ground, places in it a sufficient amount of food, lays an egg, and closes it up. In the case of bees, the food consists of honey; in that of wasps, the larva requires animal food, and the mother therefore places a certain number of insects in the cell, each species having its own special prey, some selecting small caterpillars, some beetles, some spiders. *Cerceris bupresticida*, as its name denotes, attacks beetles belonging to the genus Buprestis. Now if the Cerceris were to kill the beetle before placing it in the cell, it would decay, and the young larva when hatched would find only a mass of corruption. On the other hand, if the beetle were buried uninjured, in its struggles to escape it would be almost certain to destroy the egg. The wasp has, however, the curious instinct of stinging its prey just in the centre of the nervous system, thus depriving it of motion, and let us hope of suffering, but not killing it; when, therefore, the young larva leaves the egg, it finds ready a sufficient store of wholesome food. Other wasps, like the bees and ants, are social, and dwell together in communities. They live for one season, dying in autumn, except some of the females, which hybernate, awaking in the spring and forming new colonies. Even these, however, under ordinary circumstances, never live through a second winter. One specimen which I kept tame through last spring and summer, lived until the end of February, but then died. The larvæ of wasps are fat, fleshy, legless grubs. When they are full grown they spin for themselves a silken covering, within which they turn into chrysales. The oval bodies which are so numerous in ants' nests, and which are generally called ants' eggs, are really cocoons, not eggs. Ants are very fond of the honey-dew which is formed by the Aphides, and have been seen to tap the Aphides with their antennæ, as if to induce them to emit some of the sweet secretion. There is a species of Aphis, which lives on the roots of grass, and some ants collect these into their nests, keeping them, in fact, just

* Linnæan Transactions, 1863—"On the Development of Chloeon."

as we do cows. One species of red ant does no work for itself, but makes slaves of a black kind, which then do everything for its masters.

Ants also keep a variety of beetles and other insects in their nests. That they have some reason for this seems clear, because they readily attack any unwelcome intruder; but what that reason is we do not yet know. If these insects are to be regarded as the domestic animals of the ants, then we must admit that the ants possess more domestic animals than we do. But on this and many other points connected with ants we require additional information.

The Strepsiptera are a small, but very remarkable group of insects, parasitic on bees and wasps. The larva (Pl. 4, Fig. 8) is very minute, six-legged, and very active; it passes through its transformations within the body of the bee or wasp. The male and female are very dissimilar. The males are minute, very active, short-lived, and excitable, with one pair of very large membranous wings. The females (Pl. 3, Fig. 8), on the contrary, are almost motionless, and shaped very much like a bottle; they never quit the body of the bee, but only thrust out the head of the bottle between the abdominal rings of the bee. JOHN LUBBOCK

(*To be continued.*)

COTOPAXI—THE FIRST ASCENT OF THE GREAT VOLCANO*

STANDING fifty miles below the equator, and a hundred west of the meridian of Washington, Cotopaxi is at once the most beautiful and the most terrible of volcanoes. From the valley of Quito it appears like a huge truncated cone, in altitude equal to five Vesuviuses piled upon each other, its summit rising 4,000 ft. above the limit of perpetual snow, its sides presenting alternate ridges and gorges ploughed by descending floods of water, and around the base for miles heaps of ruins—boulders 20 ft. square, and volcanic ashes and mud 600 ft. deep. Very seldom does Cotopaxi wake up to intense activity, for as a rule the higher a volcano the less frequent its eruptions. Generally the only signs of life are the deep rumbling thunders and a cloud of smoke lazily issuing from the crater.

On November 27, 1872, Dr. Reiss—a German naturalist, who, with Dr. Stubel, has been exploring the Valley of Quito during the last forty years—set out from Mulolo with ten peones for the south-west point of the crater. Crossing the river Cutuche at Limpiopungo, where the stream cuts through vast deposits of volcanic ashes, he reached the "Ventanillas," a dry and sterile pampa, since the porous earth retains no moisture. Here the ascent of the cone began. Following the triangular ridge that divides the deep defiles of Manzanaguaico and Pucahuaico, and whose apex reaches the snow limit, he crossed subordinate cerros and pampas, which are so many steps in the grand staircase he was ascending. Vegetation now ceased entirely, and the surface was covered with ashes and black sand. In fact, nearly the whole occidental slope of Cotopaxi, between 12,500 and 16,000 ft., presents the aspect of a dismal black desert. Progress was slow, for at every step the foot sank into the sand, which increased in depth with the ascent.

Suddenly a profound chasm, containing fresh, smoking lava, was discovered on the left. This lava-stream was the lower limit of a vast mass, which from the valley appeared like a long black line. At 2 P.M. our traveller reached the point where the two quebradas unite, marked by an immense pile of rocks. Here he encamped for the night at an altitude of 15,179 feet.

An immense stream of lava came down the cone, and near the place of encampment divided, entering the two quebradas or ravines mentioned. The lava was still warm, clouds of vapour rising along the whole extent of the stream. During the afternoon the thermometer had stood at freezing point; but in the night it fell to twenty-five degrees.

The next day Dr. Reiss attained all his hopes. Cropping out of the lava stream, but mainly disposed along the borders of it, were numerous rough stones, upon which he advanced as on the rounds of a ladder. The greatest width of the lava current before it divided was about 3,000 ft., and the estimated thickness 150 ft. The lava was entirely black and warm in all its course; its temperature being from 68° to 91°, while that of the atmosphere was 32°. This elevated temperature explains the absence of snow on this part of the slope. The gaseous exhalations from the crevices seemed to be nothing more than air mixed with vapour. This is doubtless the lava-stream which flowed in 1854, and which, by melting vast quantities of snow, caused much devastation in the valley by floods. No fissure or accumulation of scoriæ indicates the source of the lava-stream; but the altitude of the point of departure is 18,700 feet.

At 8.45 he reached the arenal, a deep mass of fine sand stretching upward at an angle of 40°. Over this he must advance, difficult as it was, for on either side were impassable fields of snow and ice. The temperature of the sand was 77°. Another stream of lava was discovered, which must have flowed with great velocity, since, instead of following the inclination of the cone, it had descended diagonally. Only the peaks of Iliniza and Chimborazo in the opposite Cordillera were visible; but above the clouds, towards the south-west, a dense mass of smoke rose perpendicularly to a prodigious height, and then by an east wind was carried off in a horizontal line westward. This came from the furious and ever-active volcano of Sangay, whose top was invisible, but whose activity was manifested in this manner. As the clouds shifted, the diversified valley and its royal mountains were spread out like a map.

It was now 10.15 A.M.; thermometer, 28°. Fumeroles abounded, giving forth sulphurous gas. And now followed a sheet of compact blue ice, inclined from 35° to 40°; but fortunately it was not smooth, but covered with myriads of points or icicles three or four inches high. Scrambling over this, and climbing over and between walls, some of immense size, suddenly Dr. Reiss reached the edge of the crater. He had reached the western part of the southern lip. The crater presented an elliptical form, the major axis lying north and south. The stones which were continually falling in from all sides, but especially from the west side, rolled together as to the bottom of a funnel; there were no signs of a level bottom. The depth, roughly estimated, appeared to be 1,500 ft. The side of the funnel least inclined, and by which alone it is possible to descend, is the south-west; but here are large fumeroles sending forth dense masses of vapour charged with gas, and having a temperature of 156°. Around these fumeroles were masses of sulphur and a deposit of gypsum mixed with chloride of lime. This is of great interest as being the first instance of a chloride being found among the products of the South American volcanoes. Humboldt thought that the absence of hydrochloric acid was a characteristic of the New World volcanoes. The barometer gave 19,660 ft. as the altitude, while the doctor's trigonometrical observations, repeated at various times from independent bases in the valley, had given him 19,496 ft. as the height of the north peak, and 19,427 ft. for the southern. Both results exceed the altitude estimated by other travellers. Humboldt made it 18,880 ft.

Dr. Reiss left the crater at 1.45 P.M., and reached his encampment at the head of the ridge in three hours and a half, just as a heavy snow-storm began. He says he felt no inconvenience from the rarefaction of the air.

* Abstract of an article by Mr. James Orton in the New York *Evening Post*, March 12, 1873.

CAPTAIN PERRIER'S GEODETIC OPERATIONS IN ALGERIA

THE idea of prolonging the French arc of meridian to Sahara by the direct trigonometrical junction of Spain and Algeria, an idea of undoubted scientific value, presented itself to the mind of Captain Perrier when he was collecting the preliminary materials for the survey of Algeria. That survey was begun at the same time as the conquest, in the middle of military operations.

The design was to calculate two great lines conforming to parallels, and transversely cut by three meridians; quadilaterals would be thus formed, completed by triangles of the first order. Only a linear chain was however drawn, except in the mountainous regions where the operations would have been attended with too many difficulties.

Map showing prolongation of Meridians from Spain to Algeria

This chain, connected with the sea by three excellent bases, would serve the purpose of adjusting and arranging the detailed operations. French geodesy thus measured an arc of latitude cutting the Paris meridian and extending from Morocco to Tunis, with a length of 990 kilometres.

The chain of first-order triangles may be divided into two parts, the first from Blidah to Tunis, measured by Captain Versigny, the other more recent measured by Captain Perrier.

The admirable choice of triangles, stations, and signals is noteworthy. Those signals have been built by the observers themselves, as there were no steeples. The precision obtained is remarkable. In the sum of the three angles of any triangle, the error is about 3″·12 (centesimal seconds) * in M. Versigny's operations (who made use of Gambey's repeating circles); the error is about 3″·07 in M. Perrier's operations, who made use of Brunner's excellent asimuthal circles. In order to measure the bases, the system of M. Porro, an Italian engineer, has been employed, in preference to the old method of Borda, and it has been followed by the best results.

* One centesimal second = 0′·33 ordinary second.

Colonel Levret proved (in 1869), by very exact calculations, that the passage by Gibraltar could be dispensed with, and that it would be possible to communicate between Spain and Algeria, in spite of the immense distance between the two continents. The entire certainty of that possibility has been proved by Captain Perrier, who has pointed out in a precise manner the names and positions of the visible summits and the length of the sides of the new chain.

It was only on October 18, 1868, that he managed to perceive the Spanish shore: he saw it from Seba Chioukh, near the mouth of the Tafna, very distinctly and without the glass. A serrated ridge was to be seen in the distance, toward the north-west, with five prominent summits. The distinctness was so perfect, that he could discern with his naked eyes the different parts of those mountains, those which were in the shade and those illuminated by the sun. He thus measured azimuths with the summit of the Tessala, the zenithal distances of the two highest points of the ridge, and the zenithal distance of the horizon of the sea.

After his return to France, he compared his measurements with the survey of Spain, made by Colonel Cuello, and concluded that he had observed the Mulahacen of the Sierra Nevada, and the peak of Sagra of the Sierra Sagra, the highest points of the Sierras of the Province of Granada.

In Spain the peaks of Sagra can be seen from Mulahacen; those mountains belong to the primordial geodetic chains of the Iberic peninsula. In Africa the points of the quadrilateral (Bem Saabia, Tessala, Filhaoussen, and Nador) are reciprocally visible, and the three last are situated in the primordial chain of Algeria.

With these points, Captain Perrier was enabled to form a chain common to Europe and Africa. Leaving the station of Seba Chioukh as superfluous, as well as the direction of Nador-Sagra as being too close to the horizon of the sea, he delineated that immense pentagon formed by the five summits of Mulahacen, Sagra, Bem Saabia, Filhaoussen, and Nador, every side and diagonal of which, except one, are the directions that are to be observed. He has even calculated and valued in round numbers the length of the sides of this geodetic chain. He has found—

	Metres.
Mulahacen-Filhaoussen .	273,400
,, Nador . . .	314,500
,, Bem Saabia .	272,200
Sagra-Filhaoussen . . .	313,300
,, Bem Saabia . .	271,000

The length of the terrestrial sides are—

	Metres.
Bem Saabia-Filhaoussen .	109,800
,, Nador . . .	104,800
Mulahacen-Sagra . . .	113,900

With those approximate numbers (and valuing at 0·08 the coefficient of refraction) he has calculated the altitudes of the two Spanish mountains. The measures thus obtained differ little from the real numbers—

	Metres.
Mulahacen	3,994
Sagra	2,398

given by Colonel Cuello, and thus furnish a new verification.

As the geodetic operations are being continued with great activity in Spain and in Algeria, we may hope that in a few years the geodetic bases of Great Britain, of France, Spain, and Algeria, reduced to the same unit of

measure, can be connected by continual chains of triangles; and the meridian line of France already prolonged north ward to the Shetland Islands, carried out in Spain by the officers of that country, will reach the African Continent and extend to the Sahara, with a length of 30°.

France will then be able to oppose to the Russian arc and to the one measured in Central Europe the French arc, which, passing over plains and very high mountains, will cross the North Sea and the Mediterranean.

There is thus considerable truth in the words of M. Faye:—"Let us not forget that the French, who are at the present time so often reproached with their geographical ignorance, are the real creators of continental or maritime geodesy, and that they have continually, since Cassini to our days, published admirable geodetic papers, which have served as models to our rivals; the truly learned men abroad have always acknowledged their value."

The map of Algeria will be constructed on the same plan as the map of France, to the scale of $\frac{1}{500000}$, but as it will be coloured, and as level curves will be substituted for hatchings, it will have considerable advantages over the latter.

M. CORNU

NOTES

THE French *Société d'encouragement* have awarded to Sir Charles Wheatstone, F.R.S., the Ampère medal for his remarkable works in theoretic and applied physics. The grand prize of 12,000 francs for the discovery most useful to French industry has been awarded to M. Pasteur, for the improvements he has introduced into the manufacture of silk, of wines, of vinegar, and of beer. A prize of 3,000 francs has been awarded to M. Gramme for the construction of an apparatus giving an electric current constant in direction and in intensity, whose electromotive force and conductibility are equal to those of an azotic acid pile of 60 or 80 elements of ordinary size, and superior both in economy and solubility to the apparatus which are at present in use.

AT the present time there are staying in England two illustrious physiologists, Prof. Kölliker and Prof. Fick, the former the renowned head of the Histological School, and the latter of the Physiological Institute in the University of Würzburg.

THE University of Cambridge has accepted a fund raised by several members of St. John's College for the purpose of founding a prize to be called the Adams Prize, for the best essay on some subject of pure mathematics, astronomy, or other branch of natural philosophy. The prize is to be given once in two years, and to be open to the competition of all persons who have at any time been admitted to a degree in the University. The examiners have given notice that the subject for the prize to be adjudged in 1875 is a Theory of the Reflection and Refraction of Light.

BY the present monthly mail a testimonial, consisting of a silver tea and coffee service, is being sent to Dr. Kirk at Zanzibar, by the Royal Geographical Society. The inscription states that it is given in recognition of the services Dr. Kirk has rendered tó his country and to science by his generosity, intelligence, and zeal in the advancement of African discovery.

MR. A. H. GARROD, B.A., has been appointed Lecturer on Zoology and Comparative Anatomy at the Charing Cross Hospital. Mr. Garrod, we believe, intends to give a course of lectures during the summer.

AT the general monthly meeting of the Royal Institution of Great Britain, on Monday, April 7, the special thanks of the members were returned to Dr. Warren De La Rue, for his donation of 100*l*. towards the expense of fitting up the new Laboratories.

THE Report to the Board of Visitors of the Astronomer Royal for Scotland, gives a satisfactory account of the work, astronomical and meteorological, done at the Royal Observatory, Edinburgh. The alterations in the observatory have been completed, and the new equatorial, referred to in NATURE some months ago, is nearly ready for use, though we are sorry to see that its efficient working is very likely to be marred from want of funds. Though much needed for various purposes, Government (with a surplus of nearly five millions!) have absolutely refused to grant any additional aid to the Edinburgh Observatory. Prof. Piazzi Smyth compares his position to that of an "unfortunate artillery officer who should have received a big gun, of perhaps the most approved wrought iron and steel construction in itself, but without means of moving it, without powder and shot; and yet should be expected by the public to be continually firing it with immense success and at all sorts of objects throughout the whole year."

WITH reference to the sum of 500*l*. placed at the disposal of the Council of the Society of Arts, through Sir William Bodkin, by a gentleman who does not wish his name to appear, for promoting, by means of prizes or otherwise, economy in the use of coal for domestic purposes, the Council have decided to offer the following prizes:—1. For a new and improved system of grate, suitable to existing chimneys as generally constructed, which shall, with the least amount of coal, answer best for warming and ventilating a room.—The Society's Gold Medal and Fifty Pounds. 2. For a new and improved system of grate, suitable to existing chimneys as generally constructed, which shall, with the least amount of coal, best answer for cooking food, combined with warming and ventilating the room.—The Society's Gold Medal and Fifty Pounds. 3. For the best new and improved system of apparatus which shall, by means of gas, most efficiently and economically warm and ventilate a room.—The Society's Gold Medal and Fifty Pounds. 4. For the best new and improved system of apparatus which shall, by means of gas, be best adapted for cooking, combined with warming and ventilating the room.—The Society's Gold Medal and Fifty Pounds. 5. For any new and improved system or arrangement not included in the foregoing, which shall efficiently and economically meet domestic requirements.—The Society's Gold Medal and Fifty Pounds.

WE understand that the scientific authorities at Berlin are preparing a manual containing the necessary information for the requirements of the various expeditions sent out by the Imperial Government to observe the transit of Venus. The information given will by no means be confined to astronomical and physical subjects, but will incorporate all the branches of natural history. We hope our Government will follow so excellent a precedent, and associate a certain number of naturalists along with the astronomical observers, especially in situations where their observations are likely to prove of value.

THE forty tanks in the Brighton Aquarium, under Mr. Savile Kent's superintendence, are now well stocked with fishes, and present a most interesting field of study to the Ichthyologist. Eight of them are devoted to fresh-water fishes, and the remaining to the marine forms. Amongst the latter are fine specimens of the herring, lump-sucker, grey, streaked and red gurnets, sting-ray, balan wrasse, cook and cork-wing wrasses, and gold-sinny. Two species of dogfish have deposited eggs in their tanks, and the embryos are in process of development. The most recent addition to the fresh-water fishes is a fine salmon, presented by Mr. Berridge, Chairman of the Usk Fisheries. The two porpoises are in excellent health, and feed well on smelts and small whitings. The large tank, 100 feet in length, and containing 110,000 gallons of sea-water, gives them ample space for their gyrations.

On Saturday afternoon last Professor Ansted was thrown with so much violence from a low basket phaeton in which he and another gentleman were driving, near Melton, that his thigh was broken, and a severe scalp wound inflicted. After being attended to by a doctor, he was removed to his house at Melton. Hopes of his recovery are entertained.

On Saturday last Canon Greenwell, of Durham Cathedral, and Professor Rolleston, of Oxford, completed a series of very interesting excavations among the ancient barrows which exist in the Goodmanham and Etton Wolds, near Beverley, Yorkshire. There is a singular absence in these barrows of the implements so frequently found with ancient human remains in many parts of the country. Not only in the present excavations, but in those formerly instituted by Lord Londesborough, implements usually associated with ancient interments are entirely wanting. Contrary also to the generality of the barrows found on the wolds, which contain chiefly unburnt remains, in this locality they are for the most part burnt. Although this part of the country seems to have been extensively peopled, as these sepulchral remains betoken, there is a singular absence of implements, whereas in the north and middle wolds flint implements are found scattered about in all directions. Stone axes and other rude implements are abundant in the rest of the wold district, but they seem to have been entirely unknown in this locality, as many persons have searched for such remains without result.

The Geographical Society of St. Petersburg has lately undertaken a new exploration of Russian territory in addition to those already carried on under its auspices. The plan consists in a minute exploration, under the leadership of M. Tschekanowsky, of the area between the lower affluents of the Yenisei and the Lena, embracing the basin of the river Olenek, which represents an important deficiency in the known portion of Eastern Siberia. Two years will be occupied in the exploration. During the first the expedition will descend the Lower Tunguska, and will reach Irkutsk by the Yenisei. During the second year it expects to reach the sources of the Olenek by sledges, to descend that river to its mouth, and then cross over to the Lena, and return by this river to Irkutsk.

Those who are interested in the mental advancement of women, should refer to the March number of the *American Naturalist*, in which they will find that the first article, on "Controlling sex in butterflies," is written by Mrs. Mary Treat. This lady has prosecuted her inquiries in a truly scientific spirit, and she records her results with the greatest precision and accuracy. An outline of her argument will be found in our notice of the periodical in which it appears.

Dr. Brown-Sequard has started a new journal, the *Archives of Scientific and Practical Medicine*, published at New York and London on the 15th of each month. His sub-editor is Dr. E. C. Seguin. This periodical will chiefly contain original papers on subjects belonging to every branch of the medical sciences. It will also comprise *résumés* of English and foreign papers, reports from the author's laboratory, and reviews of modern works on kindred subjects. The first number for January, which is beautifully printed, contains 100 pages, with one plate. In it Dr. Brown-Sequard contributes a paper on "Effects of Injuries of Nerves," and there are others by Dr. Seguin, Mr. Dupuy, Dr. Sands, Dr. Mary Putnam, and several able medical authors.

Petermann's *Mittheilungen* thus speaks of the refusal of Government to grant an Arctic expedition this year :—"England, with her enormous wealth, her multitude of ships, sailors, and facilities for equipment, but above all with her great experience, could easily have sent out such an expedition, and with more prospect of success than any other nation ; but the English Government, which appears to carry parsimony further than any other, has refused the request, at least for this year. But it is to be hoped that the undertaking, for which Government was also petitioned in 1865, will at last be afloat in 1874."

At the meeting of the French Academy last week, M. Jamin exhibited a magnet which he had constructed to carry upwards of twenty-two times its own weight : it weighs 2 kilogrammes and carries 45. Hitherto the greatest carrying power attained in artificial magnets has been from four to five times their own weight. M. Jamin has obtained this unprecedented result by substituting for the very thick plates hitherto employed, a sufficient number of very thin plates superposed on each other, and all thoroughly magnetised. One result of this achievement will be that the volume and weight of magneto-electric machines can now be diminished to a very great extent.

A very full notion of the rapid material progress of Victoria in almost every direction may be obtained from the Official Catalogue of Exhibits of the Victoria Exhibition, opened at Melbourne in Nov., 1872. The entries number 1,682, and though there are very few connected directly with science, it would be unjust to form from this fact a low estimate of the progress made in scientific discovery by the colony; an investigation of the entries in the various departments shows that the principles of science have been abundantly taken advantage of in them all. It is gratifying to find, from the patent statistics, that every year shows an increase in the number of inventions connected with agriculture and manufactures, while the mining resources of the country continue to occupy a large share of the attention of inventors. The compiler of the catalogue claims with justice that Victoria has contributed a considerable amount of valuable data to various departments of science. Appended to the catalogue is an interesting essay on "Mining and Mineral Statistics, with Notes on the Rock Formations of Victoria," by Mr. R. Brough Smyth, F.G.S., Secretary for Mines for Victoria. A preliminary note gives some satisfactory statistics as to the progress of the Industrial and Technological Museum of Melbourne, which was opened in September 1870.

The *Australian Mechanic*, in an article on "Science in the South," thinks "there is good reason for hoping that the time is rapidly advancing when even in Australia the enthusiasm of science will become a wide-spread sentiment, and when a deep and genuine interest will be taken in questions of a purely abstract kind." The *Mechanic* thinks it possible that ere long the Australians "may have the satisfaction of hearing a Tyndall, a Huxley, an Owen, and their worthy fellow-labourers expounding to delighted audiences in the Melbourne Athenæum, 'the fairy tales of science.'"

The first number of *Cosmos*, the new Italian geographical journal, is handsome and well printed, and the contents creditable. There is a long article on recent expeditions to New Guinea, illustrated by a well-constructed map ; and, of course, another long article on African exploration, also accompanied by a map. Another longish article is the first of a series on the Russian possessions in Central Asia. Altogether the first number of *Cosmos* is satisfactory, and we wish it a long career and a wide circulation.

The Italian Geographical Society, by a unanimous vote, has conferred upon the Commendatore Negri Christoforo, who has so long and so perseveringly promoted geographical science among his countrymen, the title of perpetual president of the Society.

Messrs. Chapman and Hall have sent us an elaborately constructed but perfectly intelligible "Table of British Strata,"

showing their order of superposition and relative thickness. Although the division into systems, series, and formations are very detailed, the size of the chart is such, and the use of colours is so judicious, that there is little danger of it causing perplexity and confusion to the young student; the plan seems to us admirably clear and useful, and the table is in the highest degree creditable to its constructor, Mr. H. W. Bristow, F.R.S., F.G.S., director of the Geological Survey of England and Wales. It is intended for the use of schools, but we are sure it will be welcomed by many geological students who have long left school.

M. FELIX PLATEAU describes in *Les Mondes*, an ingenious process, of his own invention, for drawing on paper white lines on a black ground—a method so frequently used for scientific illustrations—by means of which both author and artist will be able to judge of the effect of such an illustration before putting it into the hands of the engraver. A piece of thickish paper, as smooth as possible, a little larger than the intended illustration, is heated, say by laying it, with proper precautions against being injured, on the top of a stove, and a piece of bees-wax is rubbed over it until the paper is completely covered with a thin coating. A piece of glass, the size of the paper, is blackened by being held over a candle, and when thoroughly cooled it is laid on the waxed paper and rubbed firmly with the fingers, the result being that a blackened surface is produced on the paper, on which any design can be traced with a needle for the finer lines, or the back of a steel-pen for the thicker ones.

A GREAT international horticultural exhibition is to be held at the Alexandra Palace on May 24 and five following days, on the occasion of the palace being opened to the public.

GENERAL COMSTOCK'S "Annual Report of the Survey of the North and North-Western Lakes" of America for the year ending June 1872, contains the results of much well-planned and thoroughly well-performed work. A well-constructed map illustrates the many typographical and hydrographical data. One point we may mention is that General Comstock has come to the conclusion, as the results of several years' observations, that the moon and sun undoubtedly cause tides in Lake Michigan, though the rise of level is very small indeed; the combination of the two at syzigies giving a tide somewhat less than 0·12 of a foot.

DR. B. W. RICHARDSON, F.R.S., has been elected by the President and Council of the Royal Society, Croonian Lecturer on the subject of muscular motion.

AMONG the Candidates for the professorship of Anatomy to the Royal Academy are Dr. B. W. Richardson, F.R.S., and Mr. John Marshall, F.R.S.

THE *Academy* understands that Mr. Moggridge, author of "Harvesting Ants and Trap-door Spiders," recently reviewed in NATURE, has deposited specimens of the animals and their nests in the British Museum, and that they are exhibited in one of the public galleries.

THE additions to the Zoological Society's Gardens during the last week include a black Cuckoo (*Eudynamys sp?*) from Madagascar, and a Seychellean Sternothere (*Sternothaera subniger*) from the Seychelles, presented by Commissioner H. C. St. John; four Spanish Terrapins (*Clemmys leprosa*), and six Greek land-tortoises (*Testudo græca*) from Morocco, presented by Sir J. Drummond Hay, K.C.B.: a Vulpine Squirrel (*Sciurus vulpinus* var *capistratus*) from S. America, presented by Mr. G. Moore; a Barbary Ape (*Macacus inuus*) from N. Africa, deposited by Lord Calthorpe; three Barbary Sheep (*Ovis tragelaphus*) born in the Gardens; a De Filippi's Meadow Starling (*Sturnella defilippi*) from Rio de la Plata, and a Black Kite (*Milvus migrans*), European, purchased; and two variegated Touracons (*Schirorhis africana*) from W. Africa, received in exchange.

PREHISTORIC CULTURE OF FLAX

DR. OSWALD HEER, the eminent botanist, and one who has devoted so much attention to the structure and history of fossil plants, publishes an article upon flax and its culture among the ancients, especially the prehistoric races of Europe. His memoir may be summarised as follows: First, flax has been cultivated in Egypt for five thousand years, and that it was and is one of the most generally diffused plants of that country. It occupied a similar position in ancient Babylonia, in Palestine, and on the Black Sea. It occurred in Greece during the prehistoric period, and at an early date was carried into Italy, while its cultivation in Spain was probably originated by the Phœnicians and Carthaginians. Second, it is also met with in the oldest Swiss lacustrine villages, while, at the same time, no hemp nor fabrics manufactured from wool are there to be found. This is considered a remarkable fact, since the sheep was one of the oldest domestic animals, and was known during the stone period. The impossibility of shearing the fleece by means of stone or bone implements is supposed to have been the reason why woollen fabrics were not used. It is thought probable that the skin, with its attached wool, was probably made use of for articles of clothing. Third, the lake dwellers probably received flax from Southern Europe, from which section fresh seeds must have been derived from time to time. The variety cultivated was the small, native, narrow-leaved kind from the coast of the Mediterranean, and not at all that now raised in Europe. It must, therefore, have been cultivated also in Southern Europe, although Dr. Heer could not ascertain among what people and at what age this took place. If this could be ascertained it would be an important point in the determination of the antiquity of the lake dwellers. Fourth, at the time of the empire both summer flax and winter flax were cultivated in Italy, as now, but in what form it was grown in ancient Egypt is not determined. It is thought probable that the narrow-leaved variety was first introduced, and after that the Roman, and then the common varieties followed. The common plant has doubtless arisen from the cultivation of the narrow-leaved, while the Roman winter flax and the *Linum ambiguum* constitute the intermediate stages. The original home of the cultivated flax was therefore along the shores of the Mediterranean. The Egyptians had probably cultivated it, and from them its use was doubtless disseminated. It is possible that the wild variety and the winter flax were grown elsewhere at the same time, when the cultivated variety had long since driven them out of use in Egypt.

SCIENTIFIC SERIALS

IN the *Journal of Botany* for February Dr. Trimen describes one of the most interesting additions recently made to the British flora, *Juncus pygmæus*, a well-known European species, discovered by Mr. W. H. Beeby in the already very rich locality of Kynance Cove, Cornwall. The article is accompanied by a good drawing. Mr. J. G. Baker gives a description of the little known *Rosa appennina*. In geographical botany Dr. W. M. Hind contributes a list of plants of North Cornwall. Mr. W. Phillips's notes on the blue reaction given by iodine in certain fungi may furnish a useful discrimination of difficult species. In the March number Mr. Worthington Smith gives a description, with coloured plate, of several new Hymenomycetous fungi from stoves; and Mr. J. A. Lees a useful paper on the peculiarities of plant-distribution in the neighbourhood of Leeds. Dr. H. F. Hance has an article on the "Ch'ing Muh Hsiang" or "Green Putchuk" of the Chinese, derived from a species of Aristolochia, the paper being illustrated by a copy of a native drawing. In both these numbers are also a variety of selected articles, short notes, and memoranda. We are glad to see this interesting journal taking so increasingly useful a place among our scientific periodicals.

AMONG the numerous articles of interest in the *Scottish Naturalist* for January (commencing the 2nd volume) we may single out especially, "On the occurrence of the hooded seal (*Cystophora cristata*) at St. Andrews," by Mr. R. Walker; a commencement of an article on Scottish gall-making insects, by Mr. P. Cameron, jun., illustrated by a beautiful coloured plate of *Nematus gallicola*; and a paper on the recent remarkable abundance of *Vanessa Antiopa*, the "Camberwell beauty," in this country, by the editor, who sums up strongly in favour of the native rather than the foreign origin of the insects captured in

this country last year. We have also a continuation of the "Insecta Scotica," in instalments of the Lepidoptera of Scotland, by Dr. Buchanan White, and the Coleoptera of Scotland, by Dr. D. Sharp.

THE *Journal* of the Royal Geological Society of Ireland, vol. iii. part 2, N. S. (vol. xiii. part 2) contains :—Reply to the observations in Mr. Kinahan's paper "On the Carboniferous Rocks of Iceland," by Prof. Ed. Hull, F.R.S. (Abstract) ; On *Phaneropleuron Andersoni* (Huxley) and *Uronemus lobatus* (Agas.), by Prof. Traquair, M.D. (plate v.) ; Additional Notes on the fossil Flora of Iceland ; On *Filicites plumiformis* (Baily) from carboniferous limestone near Wexford, by W. H. Baily (plate vi.) ; Notes on the Carrara marble quarries, by Prof. E. Hull ; On a remarkable fault in the New Red sandstone of Rainhill, Lancashire ; and observations on the results determined by the Royal Commission into the Coal Resources of Great Britain and Ireland, by Prof. E. Hull ; Sketch of the physical geology of North Clare, by W. H. S. Westropp ; On tertiary iron ore in the County of Londonderry, by G. H. Kinahan ; and Notes on Woodwardite, by Prof. J. E. Reynolds.

THE *Monthly Microscopical Journal* for April is an excellent number, containing several valuable papers. Mr. Wenham gives his new formula for microscope object-glasses, recently read before the Royal Society. Till recently high objectives have been formed of eight lenses, a front and back triplet with a middle doublet, consequently the rays of light are subject to error arising from sixteen surfaces of glass. The author some time ago substituted a single thick plano-convex for the anterior triplet, and in so doing reduced the number of reflecting surfaces to twelve, improving the instrument so much that his system has been generally adopted. In the new object-glass the number of lenses is still further reduced to five, and the surfaces consequently to ten ; in it the front plano-convex remains, the back triplet is made the centre of the system, and the over corrected rays which leave it are rendered parallel at the point of emergence by a long focus plano-convex glass. In this combination therefore the whole correction is performed by a single concave of dense flint, and therefore two single lenses of crown, whose foci bear a definite relation to each other. Dr. Urban Pritchard's excellent observations "On the structure and function of the Rods of the Cochlean in man and other animals" are given *in extenso*. Dr. E. Hofman's paper on "Hair in its microscopical and medico-legal aspects" is translated, forming a concise summary for the student of forensic medicine. Dr. Maddox makes "Some remarks on a minute plant found in an incrustation of carbonate of lime," which he considers to be of the genus *Botrydium*, and names *B. minutum*.

THE *American Naturalist* for March contains an article by Mrs. Mary Treat, on "Controlling Sex in Butterflies." The authoress, as the result of an accident, observed that the larvæ of *Papilio asterias* when underfed almost invariably developed into male butterflies, but that when freely supplied with their favourite diet, they almost as certainly developed into females. She repeated these experiments on large numbers with the same result, and has verified them on *Vanessa antiopa* and the moth *Dryocampa rubicunda*. Mr. A. S. Packard criticises these results, and shows that the earliest indications of the sexual glands appear when the larva is but little developed, and that they are often fully formed when it is adult. There are papers by Profs. Marsh and Cope on the extinct Ungulata of the Wyoming district, in which some dates of publication are fully discussed. Among the other papers are, Prof. Perkins on "The Flying Squirrel ;" C. Ran, on "Indian Netsinkers and Hammerstones ;" and R. Ridgway, on "The Vegetation of the Lower Wabash Valley."

Ocean Highways, New Series, No. 1.—The new form of this valuable journal is a great improvement on the original unhandy form, though we do not think the increase in bulk is very great. This number is a particularly interesting one. The first article is called forth by the Khiva expedition, and gives a summary of the commercial and political history of the Caspian, and the region to the eastward ; it is illustrated by two good maps. "The Great Rivers of China" is the title of a short article by Dr. F. Porter Smith, while Mr. C. E. Austen, C.E., contributes a useful article, accompanied by an excellent map, on "Railways in Asia Minor." Mr. D. Hanbury has a short article on myrrh, the object of which is to induce travellers to collect data for its botanical elucidation. Prof. Mohn describes the origin and history of the Meteorological Institute of Christiania ; a map by the same gentleman is given, illustrating the explorations by Norwegian Captains about Spitzbergen in 1872 ; accompanying which is a short editorial paper on Wiche's Land, defending the name given to it by Edge in 1617. One very interesting paper is by Mr. T. F. Hughes, on "Formosa and its southern Aborigines." "In this fair island of the distant eastern seas," he says, "there is still a mine of discovery and information awaiting the cunning hand of the scholar and traveller." Reviews, notes, reports, correspondence, &c., complete this interesting number.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 3,—"On the Structure of Muscular Fibre," by E. A. Shafer.

"Note on the Synthesis of Marsh Gas, and the Electric Decomposition of Carbonic Oxide," by Sir B. G. Brodie, F.R.S.

"On an Air Battery," by Dr. Gladstone, F.R.S., and A. Tribe.

Chemical Society, April 3.—Dr. Odling, F.R.S., &c., president, in the chair.—A paper on "A method of determining with great exactness the specific gravity of liquids," was read by the author, Dr. Sprengel. The instrument, consisting of a U-shaped glass tube terminating in capillary tubes bent at right angles, is very delicate when proper precautions are taken.—The second paper, entitled "Researches on the action of the copper-zinc couple on organic bodies :—No. II. on the iodides of methyl and amyl," by J. H. Gladstone, F.R.S., and A. Tribe, is a continuation of the authors' researches on this subject, an account of which they communicated to the Society some short time ago.—Dr. C. R. A. Wright then read a memoir "On Cymene from various sources," in which he gives the results of his examination of cymene prepared from eight different sources, showing them to be identical.—The last paper was by Dr. H. E. Armstrong, being No. XI. of "Communications from the Laboratory of the London Institution ; action of the acid chlorides on nitrates and nitrites—Part I. Acetic chloride."

Zoological Society, April 1.—Mr. R. Hudson, F.R.S., vice-president, in the chair.—A communication was read from Dr. J. S. Bowerbank containing a description of the brain and of a portion of the nervous system of *Pediculus capitis*.—A communication was read from Dr. J. E. Gray, F.R.S., containing remarks on the genera of Turtles (*Oiacopodes*), and especially on their skeletons and skulls.—A second communication from Dr. Gray contained the description of the skull of *Sternothaerus*.—Dr. A. Günther, F.R.S., read descriptions of three new species of Flying Squirrels, proposed to be called *Pteromys tephromelas*, from Penang, *P. phæomelas*, from Borneo, and *Sciuropterus pulverulentus*, from Penang and Malacca.—Mr. O. Salvin made some remarks on the tail-feathers of the birds of the genus *Momotus*, and on the mode in which their peculiar form had originally arisen.

Geological Society, March 26.—His Grace the Duke of Argyll, K.T., F.R.S., president, in the chair. The following communications were read :—1. "Synopsis of the younger formations of New Zealand," by Capt. F. W. Hutton, F.G.S., of the Geological Survey of New Zealand. In this paper the author gave a summary of the Tertiary and later Secondary formations of New Zealand. He stated that he had been able to determine 375 species of true Mollusca, 12 of Brachiopoda, and 18 of Echinodermata from the Tertiaries ; and under each of the formations which he recognises he gave the number of species of true Mollusca found in it, indicating the number of recent species, and of those belonging to other formations occurring in each. He also noticed the range and distribution of the various formations. The Tertiary groups of strata distinguished by the author are, in descending order, as follows :—I. Pleistocene. II. Pliocene : 1, the Newer Pliocene or Whanganui group : 2, the Older Pliocene or Lignite group. III. Miocene : 3, Upper or Arvatere group ; 4, Lower or Kanieri group. IV. Oligocene : 5, Upper or Hawke's Bay group ; 6, Lower or Waitewata group, V. Eocene : 7, Upper or Ototara group ; 8, Lower or Brown Coal group. As belonging to the Mesozoic series, the author also described beds of Danian age, under the name of the Waipara formation. A species of *Belemnitella* occurs in beds belonging to the Ototara group, and also in the Waipara formation. Volcanic action commenced in the North Island during the deposition of the Waitewata group, and has since been almost continuous in the northern, western, and central parts of the

island. In the South Island the volcanic formations appear to belong to the later Cretaceous, Oligocene, and Miocene periods. The volcanic rocks of the Chatham Islands belong chiefly to the Upper Oligocene.—2. "On the Tree-ferns of the Coal-measures, and their relations to other living and fossil forms," by Mr. W. Carruthers, F.R.S., F.G.S. The author pointed out that there existed in the Coal-measures two very distinct kinds of fern-stems, each represented by several species. The first group had a stem-structure like that of living tree-ferns. In them the vascular elements of the stem formed a closed cylinder round the pith; and the vascular bundles for the leaves were given off from the out-turned edges of the cylinder, where, at regular intervals, corresponding to the position of the leaves, narrow meshes occur for this purpose. In the second group the stems differed from the other group chiefly in having the ends of the vascular plates, as seen in the transverse section, turned inwards, and having the bundles of the leaves formed in a complete condition in the axis of the stem.—3. "Notes on the Geology of Kazirùn, Persia," by Mr. A. H. Schindler. In this paper, which accompanied a series of specimens presented to the Museum of the Society, the author described the section presented by the hills in the neighbourhood of Kaizirùn. The general surface was described as consisting of nearly unfossiliferous Post-tertiary deposits, immediately beneath which is an unstratified marine deposit containing a great abundance of fossils, among which are species of *Ostrea*, *Pecten*, and *Cidaris* (?). Below this deposit is a succession of strata, repeated several times in the hills, and at the bottom of the series in each case is a bed of gypsum. The spaces between the recurrent series are filled up with conglomerates. Beneath the gypseous series is a formation of compact limestone, which rises to a height of about 1500 feet both north and south of the plain of Kazirùn; its beds dip 25°, and their strike is from N.E. to S.W.

Royal Microscopical Society, April 2.—Mr. Charles Brooke, F.R.S., president, in the chair.—A paper was read by Mr. Henry Davis on a new species of *Callidina* (*C. vaga*), the distinctive characteristics of which were fully described and living specimens exhibited. Mr. Davis also detailed a series of experiments upon the dessication of rotifers, the results of which tended to prove that although they could not be revived after having been once actually dried up, it was quite possible for them to survive what was generally accepted as actual dessication, and that they would resist not only a sustained temperature of 200°, but also exposure for a long period in the exhausted receiver of an air-pump with sulphuric acid. He pointed out and proved by experiment, that during the process of drying the gelatinous matter which was secreted by these rotifers contracted around them, forming an impervious envelope and effectually preserving within it sufficient moisture to sustain life.—A communication was read from Mr. Parfitt, of Exeter, descriptive of a presumed new animal, apparently related to the annelids.—A fine preparation of malpighian capsules from the kidney, was exhibited and described by Mr. Stewart.

Anthropological Institute, April 1.—Prof. Busk, F.R.S., president, in the chair. The president read "Remarks on a Collection of Ancient Peruvian Skulls presented to the Anthropological Institute, by Mr. T. J. Hutchinson, H.B.M. consul at Callao." The skulls were collected by the Consul from the "Huacas" near Santos, to the north of Callao, which were considered by him to be those of Chinchas, or Huancas, or perhaps of Quichmas, or Aymaras, all of which tribes are now probably absorbed into the Cholas, a Mestizo race; from Ancon, from Pasamayo, about thirty miles north of Callao, and from Cerro del Oro in the Canete Valley—in all 156 specimens. After giving further detailed descriptions on the authority of Consul Hutchinson, the author passed to the consideration of the characters presented by the crania exhibited. Such of the specimens as he had been able to measure yielded the following results:—"The mean length was about 6·25 in., and the breadth 5·6 in., giving a cephalic or latitudinal index of ·905, only two falling below ·800. In that estimate were included both normally-shaped and artificially compressed skulls. The cephalic index of the supposed normally shaped, was ·873, the greatest being ·935, and the least ·812; and of the clearly artificially deformed, ·979; the greatest being 1·32, and the least ·861. Those figures showed how very much the latitudinal index was exalted by the fore and aft compression of the skull. The altitudinal index of the normal skulls was ·843, that of the compressed ·878. The mean capacity of the larger and male skulls appeared to show a result of about 80 cubic in. equivalent to brain of about 45 oz. roughly estimated, which result indicated that the crania were of small size.—The president communicated a paper by Mr. J. M. Reade, "On a human skull and fragments of bones of the Red Deer found at Birk Dale, Southport."

Meteorological Society, March 19.—Dr. Tripe, president, in the chair—The president informed the meeting that at the last meeting of Council a letter was read containing Mr. Glaisher's resignation of the Secretaryship, and that after much consideration the Council had accepted it with great regret; that they had then appointed Mr. Cator to the vacant office for the remainder of the session, and elected Mr. Glaisher to the seat on the Council thus rendered vacant, which he was glad to say Mr. Glaisher had accepted.—The first paper read was by Mr. R. H. Scott, F.R.S., "On some results of weather telegraphy," in which he laid before the Society some of the special circumstances connected with that service. He stated that the information received was insufficient, both in quantity and quality, to give a complete idea of the weather, and showed how any serious extension of the system would entail greatly increased expenditure, citing the very large cost (50,000*l.* per annum) of the American signal service, the most perfect in existance. He drew attention to the frequency of telegraphic errors, and the serious results arising therefrom. He next proceeded to discuss the probability of our deriving benefit from additional reports from the Azores, &c., and showed by actual investigation that such reports would not be of immediate use to these islands in regard of giving notice of advancing storms. The modes of conveying warnings to ships were next mentioned, and Mr. Scott stated his belief that ultimately Admiral Fitzroy's drum and cones would be adopted, though not perhaps in the significations originally attached to them.—The other paper was by Mr. W. Marriott, "On the Barometric Depression of January 24, 1872." This depression occurring in the early morning hours, very few observations had been made at the time of lowest pressure; but from those which he had received, the depression appears to have first touched the English coast near Falmouth about midnight, and to have passed along the coast to Upwey, which was reached about 3 A.M.; it then took a northerly course and passed near Birmingham at 6 A.M., after which it crossed Derbyshire, Nottinghamshire, and Lincolnshire, and passed out of the Humber between 10 and 11 A.M. He stated, however, that the evidence was insufficient to prove that this was its actual course, or whether it merely passed over England in a N.E. by N. direction at a uniform rate of about 30 miles an hour. The lowest readings of the barometer were 28·18 in. at 4.30 A.M. at Clifton, and 28·179 in. at 5.20 A.M. at Evesham. The paper concluded with a few remarks on former depressions.

Institution of Civil Engineers, March 25.—Mr. T. Hawksley, president, in the chair.—"The Mont Cenis Tunnel," by Mr. Thomas Sopwith, jun., M. Inst. C. E. This communication might be considered as supplementary to a former paper read in 1864—(Min. Proc. Inst. C. E., vol. xxiii., p. 258)—and described, (1) the Tunnel, as completed, with statistics obtained either by actual observation or from the Engineers in charge, or from official publications of the Italian Government; (2) the principal changes which had been introduced in the works and machinery underground and at the surface since the summer of 1863.

MANCHESTER

Literary and Philosophical Society, March 18.—Dr. J. P. Joule, F.R.S., president, in the chair.—"Observations on the Rate at which Stalagmite is being accumulated in the Ingleborough Cave," by W. Boyd Dawkins, F.R.S. He thinks it evident, from his researches, that the value of a layer of stalagmite, in fixing the high antiquity of deposits below it, is comparatively little. The layers, for instance, in Kent's Hole, which are generally believed to have demanded a considerable lapse of time, may possibly have been formed at the rate of a quarter of an inch per annum, and the human bones which lie buried under the stalagmite in the cave of Bruniquel are not for that reason to be taken to be of vast antiquity. It may be fairly concluded that the thickness of layers of stalagmite cannot be used as an argument in support of the remote age of the strata below. At the rate of a quarter of an inch per annum 20 feet of stalagmite might be formed in 1,000 years.—"On Methyl-alizarine," and Ethyl-alizarine," by Edward Schunck, Ph.D., F.R.S.—"On the Transition from Roman to Arabic numerals (so-called) in England," by the Rev. Brooke Herford.—"Notes on the Vic-

toria Cave, Settle," by William Brockbank, F.G.S. For various reasons, he submitted, there is no ground for the theory of glacial action as put forth by Messrs. Boyd Dawkins and Tiddeman, but on the contrary that the filling of the Victoria Cave was the work of long ages, by the action of running water, and that there is no reason to suppose that the remains found in it are older than the glacial epoch.—The President exhibited a syphon barometer, the peculiarity of which consisted in the introduction of a small quantity of sulphuric acid over the ends of the mercurial column.—Mr. Spence, F.C.S., communicated to the Society the result of an experiment in heating a diamond, which will considerably modify the general impression as to that gem being combustible only at an extremely high heat. A friend of his had brought over a number of diamonds from the African mines. Some of these were what is called "off colour," not being purely white, and he put one of these into Mr. Spence's hands to try some experiments for displacing the colour if practicable. This diamond, the size of a small pea, was immersed in fire-clay in a small crucible, the clay being mixed with a little carbonate of soda and hydrate of lime; the crucible was then placed in a muffle, and for three days and nights exposed to a heat, which at no time was beyond a low cherry red. After cooling, the crucible was broken, and the lump of hardened fire-clay was carefully broken up to extract the diamond; after two or three fractures of the lump an impression or hole in the indurated clay was discovered just at the spot where the diamond should have been, but not a vestige of the precious stone remained.

DUBLIN

Royal Irish Academy, March 15.—The Rev. Prof. Jellett, B.D., president, in the chair. The annual report of the council was read by Dr. Ingram, secretary to council. The election of the president and members of council was proceeded with, when the Rev. J. H. Jellett, B.D., was re-elected President.

Royal Geological and Zoological Societies of Ireland. A joint meeting of these societies was held on Wednesday evening, March 12. Colonel Meadows Taylor read a paper on the coal fields of Central India.—Prof. Edward Hull, F.R.S., read a paper on the Microscopical Structure of the Limerick Carboniferous Trap Rocks.—A Geological Map of New Zealand, and a fine recent specimen in spirits of *Pentacrinus Mülleri* Orst were exhibited.

PARIS

Academy of Sciences, March 31.—M. de Quatrefages, president, in the chair.—The following papers were read:—On the theory of the normal magnet, and on the means of indefinitely increasing the force of magnets, by M. J. Jamin.—On the carpellary theory of the Ranunculaceæ, by M. A. Trecul.—On the proposed apparatus for pumping out and elevating water by means of the action of waves on the shores of the Mediterranean, by M. A. de Caligny. The author has suggested a means of utilising the force of the waves for the above purposes.—New papers on the shock of earthquake in Italy, observed on the 12th of March, 1873, by M. P. de Tchihatchef.—The Academy then proceeded to elect a member in the place of the late Marshal Vaillant. After two votings, in which no candidate obtained an absolute majority, a ballot was proceeded with, when M. Cosson obtained 31 and M. de la Gournerie 30 votes. M. Cosson was then declared duly elected.—A report on two memoirs on the silicified vegetables of the Autun coal measures, by M. B. Regnault, was then read, and followed by M. Roger's fourth memoir on capillary phenomena, which dealt with the mathematical nature of the subject.—On a new method of optically determining the velocity of projectiles, by M. M. Deprez. The method consists in attaching a magnesium fuse to the projectile and observing its flight by means of two telescopes. The method is an application of that used for meteors.—The Secretary read a number of extracts from a paper on a new classification of clouds, by M. Poey.—On certain points in M. Faye's theory of the solar spots, by M. Tacchini. Father Tacchini thinks that the hydrogen carried down by cyclones, according to M. Faye's theory, would become so violently heated that it would rush back with such force as to destroy the cyclone, and also that if such a process really occurred the gas would carry up with it metallic vapours; as these are not generally visible in prominences, he thinks the explanation untenable.—On the foci (*faisceaux*) of circles, by M. Ribaucour.—On the spectrum of boric anhydride, by M. Lecocq de Boisbaudran.—On alcohol and normal acetic acid from milk considered as products of the functions of microzymes, by M. A. Béchamp.

DIARY

THURSDAY, APRIL 10.

MATHEMATICAL SOCIETY, at 8.—On Systems of Porismatic Equations, Algebraical and Trigonometrical; Note on Epicycloids and Hypocycloids; Locus of point of concourse of perpendicular Tangents to a Cardioid; Elliptic motion under acceleration constant in direction: Prof Wolstenholme.—On the calculation of the Value of the theoretical unit-angle to a great number of decimal places: Mr. J. W. L. Glaisher.

SATURDAY, APRIL 12.

ROYAL BOTANIC SOCIETY, at 3.45.

TUESDAY, APRIL 15.

STATISTICAL SOCIETY, at 7.45.

WEDNESDAY, APRIL 16.

SOCIETY OF ARTS, at 8.—On the Condensed Milk Manufacture: L. P. Merriman.

METEOROLOGICAL SOCIETY, at 7.—On a proposed new form of Rain Gauge, "The Atmospileometer:" J. J. Hall.—Discussion on the Report of the Proceedings of the Meteorological Conference at Leipzig.

LONDON INSTITUTION, at 7.—Third Musical Lecture: Prof. Ella.

THURSDAY, APRIL 17.

LINNEAN SOCIETY, at 8.—Burmese *Orchideæ*, from the Rev. C. P. Parish: Prof Reichenbach.—Perigynium of *Carex*: Prof. McNab.

CHEMICAL SOCIETY, at 8.—On Heat produced by Chemical Action: Dr. Debus, F.R.S

NUMISMATIC SOCIETY, at 7.

ZOOLOGICAL SOCIETY, at 4.

BOOKS RECEIVED

ENGLISH.—A Manual of Photography. 8th edit.: G. Dawson (Churchill).—Electricity and Magnetism. 2 vols: C Maxwell (Macmillan).—Flies and Fly-fishing: Capt. St. J. Dick (R. Hardwicke).—A Catalogue of the Collection of Cambrian and Silurian Fossils in the Geological Museum of the University of Cambridge: J. W. Salter, Prof. A. Sedgwick, Prof. Morris (University Press, Cambridge).—Fever and Cholera from a new point of view: A. Smith (Calcutta).—Illustrated Guide to the Fish Amphibian. Reptilian and supposed Mammalian remains of the Northumberland Carboniferous Strata, with Atlas; T P. Barkas (Hutchings).—A Journey through the Caucasus and the interior of Persia: A. H. Mounsey (Smith and Elder).—A Journey to the Source of the River Oxus. 2nd edit.: Capt. J. Wood (Murray.)—Turning for Amateurs.—Birds of the Humber District: J. Cordeaux (Van Voorst).—A General System of Botany, Descriptive and Analytical: Emm. de Mout and J. Decaisne. Translated by Mrs. Hooker, Edited by Dr. Hooker (Longmans).—The Principles of Animal Mechanics: The Rev. S. Haughton (Longmans).—Field and Forest Rambles: A. L. Adams (H. S. King & Co.).

PAMPHLETS RECEIVED

ENGLISH.—The Agricultural Returns of Great Britain for 1872.—Quarterly Weather Report of the Meteorological Office, Pt. 2, April–June, 1872—A Message to the British Entomologists by the Ghost of the Rector of Barham: E. W. Janson.—Journal of Mental Science, No. 49, April: H. Maudsley and Thos. Clouston, M.D. (Churchill).—The Potato Disease, its cause and its remedy: S. Smith (Smart & Allen).—General Report on the Operations of the great Trigometrical Survey of India during 1871-2: Major Montgomerie, R.E., F.R.S.

FOREIGN—Anales del Museo Publico de Buenos Aires, 1872-73.—Report of the Commissioners of Fisheries of the State of New York.—Recherches expérimentales sur l'influence que les changements dans la pression barometrique exercent sur les phenomenes de la vie (8th note): M. P. Bert.

THE ZOOLOGICAL COLLECTIONS IN THE INDIA HOUSE

IN former days the "Hon. East India Company," in their House in Leadenhall Street, possessed a valuable Museum of Natural History. It contained specimens in all branches of science from the Company's Oriental possessions, partly contributed by public servants who had been attached as naturalists to missions and deputations sent out by the Indian Government, and partly by gentlemen of the civil and military services of the Company, as presents to the Court of Directors.

The following well-known names were amongst those who contributed to the collection:—Dr. Francis Buchanan Hamilton, Dr. Horsfield, Sir Stamford Raffles, Mr. Wallich, Mr. Reeves, Mr. McClelland, Dr. Helfer, Mr. T. T. Pearson, Dr. Falconer, Mr. Hodgson, Col. Sykes, Mr. Ezra Downes, Gen. Strachey, Col. Tytler, and Dr. Cantor. The list of contributors embraced, in fact, all those naturalists and collectors to whom science is mostly indebted for the knowledge we at present possess of the Fauna of India and the adjoining countries.

Amongst collections of special importance belonging to the East India Museum, may be noticed Dr. Horsfield's collections from Java, those made by Mr. Finlayson during Crawford's Mission to Siam, those of Col. Sykes during his survey at the Dukhun, the entomological collections made by Dr. Cantor in Chusan, and the same naturalist's collections from Singapore; the zoological collections of Sir W. Snow Harris, made during his mission to Abyssinia, and those of Commander Jones during his survey of the Euphrates and Tigris.

In 1851 the late Dr. Horsfield, who up to the time of his decease was Curator of the Museum, published a catalogue of the mammalia in the collection, which, in addition to an exact enumeration of the specimens, contains many valuable notes upon the habits, range, and other peculiarities of the species. This was followed a few years later by a catalogue of the birds of the collection, which was prepared by Mr. F. Moore, the assistant in the museum, under Dr. Horsfield's superintendence. Of the catalogue of birds two volumes were published, the first in 1854, and the second in 1858. The third, which was intended to have completed the work, has never appeared. More than a thousand species, however, are catalogued in the two first volumes, most of them represented by several specimens.

When after the Indian mutiny the absorption of the "Honourable East India Company" by Her Majesty's Government took place, the museum of the Company was moved to Fife House, Whitehall, as a temporary resting-place. The natural history collections were exhibited in this building in a very imperfect way, but it was well understood that they were only deposited here pending the construction of the new India Office, where abundance of space for their display was promised.

The time arrived when the square-towered palace in St. James's Park was finished, and the various branches of the India Office moved into it. So far, however, from there being any more space found for the natural history collections it was now discovered that there was no room for them at all. The whole of them were packed up in boxes and placed in store, and so remain to the present day, so that it is impossible to get at them for any available purpose even when the examination of a particular individual specimen is specially required.

On more than one occasion in the course of scientific work the writer has had occasion to examine some of the specimens in the collection, but has been informed that they could not be got at amongst the mass of packages. Other working naturalists have met with similar replies to their applications, and even a Russian entomologist, I have been informed, whose principal motive in coming to England was to examine some of the insects in the collection, had to return with his mission unaccomplished.

In 1871 the late Lieut.-Col. Sykes, having had his attention called to the subject by a letter addressed to the *Times*, asked the Under-Secretary of State for India in the House of Commons "when the zoological collections in the India House would be accessible to zoologists." The following is stated in the *Times* of March 15, 1871, to have been the reply given by the Under-Secretary:—

"In reply to my honourable and gallant friend, I have to say that the zoological collections belonging to the Secretary of State in Council, are, to a *certain extent*, even now available to men of science, who can readily obtain admission to examine them. They examine them however, I am sorry to say, under great difficulties, and difficulties of which I do not see the end: for even if the Secretary of State in Council were to erect on his property in Charles Street, as he has sometimes been advised to do, a building more worthy to contain the great museum and library which he possesses, than the garrets in which they are now stowed away, nearly the whole available space would be occupied by those Indian productions which it is important to bring under the notice of the commercial classes of this country, and pure science would, I fear, come off very badly."

The "*certain extent*" to which, according to this reply, the collections are "*even* now available to men of science," may be judged of from what has been already stated. But in fact, it was ultimately admitted by the Under-Secretary, after a little pressure on the part of the questioner, that the collections were "boxed up;" nor has any change been made in their condition since that period.

It must, I think, be obvious to all those who have read the statement above given that a gross wrong has been perpetrated in the present case. When the Imperial Government took possession of the late East India Company's establishment, they were manifestly bound to perform the duties attached to it. To nail up the whole of the natural history collections in closed cases, and deposit them in a cellar is a strange way of accepting the *officium cum onere*. It is a wrong, not only to the labourers in science who have occasion to consult the collections, but also to the many distinguished officers of the late Company's service, who contributed to form them. The longer the present state of things continues, the greater will the wrong become, as it is almost impossible to prevent the ravages of insects in the case of specimens of natural history of any sort that are stowed away without periodical examination.

It being, however, hopeless to expect that the India

Office, in its present economical fit, will spend the money necessary to build a Museum for the proper exhibition of its collections of manufactures and natural history, the following two solutions of the difficulty may be suggested.

(1) That an arrangement be made with the Commissioners of the Exhibition of 1851 to exhibit the collections at South Kensington, either in one of the existing buildings, or in one to be constructed for that purpose. The French have an "Exposition des Produits des Colonies" in part of the former Palais de l'Industrie in the Champs Elysées, and there is no reason why we should not follow so desirable a precedent.

(2) If this cannot be effected, the whole of the collections should be transferred to the trustees of the British Museum. It is, of course, quite certain that the trustees could not exhibit them, looking to the crowded state of their galleries in Great Russell Street. But at all events they would be thus saved from risk of further deterioration, and might be rendered accessible to working naturalists who have occasion to consult them. P. L. S.

*UNIVERSITY OARS**

III.

We have stated that in our opinion the evils of boat-racing as now practised are traceable to two causes, 1st to a misconception of the nature of the demands which it makes on the several energies of the body; and 2nd, to the system of preparation, or, as it is technically called, *training*, which is undertaken to enable the body to meet these special demands upon its energies.

In our remarks last week we stated at some length wherein lay the first of these misconceptions, namely, in the nature and extent of the effort made by the muscular system and the respiratory and circulatory system, respectively, showing that while the exertion was slight, if not actually inadequate to the requirements of the former, it was both in amount and character severe, if not absolutely dangerous, in the latter.

The origin of the first misconception, and the reason why it should have lived so long, and should still live, we think may be thus explained. When rowing was first adopted by lads at schools and young men at universities as a regular mode of exercise, and friendly matches of speed and dexterity were organised, the boats used, probably, were not greatly different in size, in shape, or in other points of construction, if in any, from those at the time in use by professional watermen; and the manner of rowing was also, very probably, after the waterman's type. If this were the case then rowing furnished abundant exercise, not only to those portions of the rower's frame which still receive a fair share of employment, but to those also which are at present virtually excluded from the task, or have a very inferior part to play in it; for the heavy, bulky, broad and deep boats, clumsy, unwieldy, and unskilfully arranged oars and rowlocks, would necessitate a slow and protracted stroke, and both upper and lower limbs would have their part to play and their work to do in dragging the oar through the water. Gradually, changes and improvements would be introduced, lessening the labour, heightening the art, until art and labour in boat propulsion attained their present positions and proportions, the former reduced to a minimum, the latter standing eminently high: but just in proportion to the prominence of these conditions are its merits as an exercise in an inverse ratio to be estimated. There was plenty of muscular exertion for the whole frame in lugging along the old-fashioned boats. There was little or no distress to heart or lungs in its protracted stroke and deliberate pace. We frankly confess that there would be little in the old style of boat-racing to create and sustain the enthusiasm at present displayed in these contests; and we are expressing no regret at the changes that have taken place, and no wish to return to their primitive, albeit safe conditions: what we do wish is to let rowing remain as it is, nay, to let it pursue its onward course of change and improvement like all other things, but to see if the old order of safety cannot be retained with these advancements, by obtaining from other sources those properties which recent changes have altogether eliminated or reduced to inefficient proportions.

To glance at the reason why the misconception regarding the actual nature of a boat-race as now rowed, should have so long existed, and should still exist, we think it needs only to be pointed out that only quite recently has any really critical inquiry been instituted on the subject, and when the results of this inquiry were made known, they savoured to the oarsman like the prescribed "nasty medicines" to the child; *i.e.* whatever good they may have been calculated to effect, they were nevertheless unpalatable, and if not actually rejected were at any rate swallowed with dislike. But rowing men are not singular in this respect, in claiming for their favourite exercise, through all its changes, in all its attributes, *perfection*; they are claiming no more than all enthusiastic votaries of a special exercise claim, and many with less excuse and less right to an indulgent hearing than the oarsman. "It gives exercise to every muscle of the body," say they, "No exercise whatever," we reply, "does this." No single exercise gives more than employment to a portion of the body, and to that portion sometimes a very inadequate share.

The errors involved in the second misconception in a great measure originate in the first, and their nature is revealed, and the manner of their connection explained as we proceed in making ourselves acquainted with it. Thus an oarsman at a given time will be called upon to row a race which will tax his bodily energies *such as he knows them, or believes them, to be*, to the uttermost; the effort will be quite exceptional in its severity and he therefore desires to prepare for it, to fortify himself for it, by every means in his power. Now it need hardly be said that if he is ignorant of the nature of the demands which the effort will make upon him, he cannot rightly prepare himself for that effort; nay, he may, and probably will, go wrong, for advice will be pressed upon him at all hands, and here at any rate, "In the multiplicity of counsel there is *not* wisdom." When it is remembered that this preparation or training embraces the administration, or use, of all the material agents which sustain life and give health and strength, it will not be wondered at that mistakes have been made in this direction, and that man should have come to speak

* Continued from p 418

of the *ordeal* (!) of training as of a trial as great if not greater than the effort itself for which the training was instituted. Thus one of Dr. Morgan's correspondents who rowed bow at Putney in 1849, Rev. D. Wauchop, Wadham College, Oxford, and a friend of our own of long standing, writes: "A curious circumstance with regard to training I would mention, and that is that one of the most sinewy and lasting men of my friends, who had been accustomed to rowing since he was little more than a child, and who was a particularly steady and temperate man, and so good an oar as to be chosen stroke for a time, never could stand training. After a few days of it he invariably broke down, and therefore never rowed in a race."

It will therefore be easily seen how great must be the advantages to rowing of clearing up what we have called the *first misconception*, in the light of its effects upon the health of the men engaged in it—the only light which would justify our having entered upon the subject at such length in the columns of a purely scientific journal. Thus while it was imagined that rowing entailed tremendous muscular exertions upon the oarsman, rules as to *diet, sleep*, and *exercise* were laid down to meet such exertions, one authority recommending men to be in bed ten or eleven hours; for diet underdone meat in vast quantities, and without vegetables—"not even a potato"—was prescribed, while exercise of any or all kinds put together was cut down to less than one hour in the twenty-four. Thus did the first misconception sustain and prolong the existence of, if it did not give origin to, the second.

The errors in *sleep* and in *diet* are being rapidly cleared away. They are destined soon to be numbered among the vagaries of the past, and in this place we may already pronounce them undeserving of serious exposure or condemnation. With the other agent of health named above, however, as affected by a want of true knowledge of the exertion undergone in rowing, namely, exercise, the case is different. The errors on this head are still many and grave, and to the correction of them we must look before we can expect to see any material improvement in the hygienic value of rowing; it is to exercise we must look to restore the lost equilibrium of rowing on the several systems of the body; to exercise we must look to equalise the partial developments of the frame now caused by rowing as exclusive of muscular exertion; to exercise we must look for that increase in vigour and power and functional capacity generally, now wanted to enable the organs of circulation and evaporation to sustain the extreme effort which they are called upon to fill during a boat-race.

We will assume that we have established that in rowing the chest and upper limbs receive an inadequate share of the exercise, and therefore in accordance with the organic law regulating material development and functional capacity,—that "*these will be in relation to employment*," —an advancement in these respects will be shown in those regions, inferior to what is observable in other parts of the body when the employment is greater. This assumption being admitted, it will also be admitted that any want of development or capacity experienced in these regions—whether in the power of the muscles aiding respiration, in the size or conformation of the thoracic cavity, or in the size, conformation or capacity of the organs which they contain,—would affect, and affect in an increasing ratio with its extent, the respiratory effort during a boat-race.

We admit that we are somewhat at issue with Dr. Morgan, inasmuch as he does not go with us so far as to acknowledge this partial division of the labour, and consequently of the reward to the parts engaged, in the act of rowing; but he *does* acknowledge that if it *did* exist, the right way to its rectification would be to supply to the parts found wanting, employment elsewhere and in other form. This is nearly all that we can desire—perhaps more than at this date we have yet a right to expect from a devoted oarsman, jealous of his craft. His language is emphatic and significant:—

"In examining patients for insurance companies, I have frequently refused the lives of young persons on the ground that their chests were narrow and shallow. In several instances, however, these thoracic defects have been corrected by a systematic course of gymnastic exercises, justifying me at a later period in recommending their acceptance. At no time and in no place could every useful variety of exercise be more advantageously carried out than at Oxford and Cambridge; they might, for the class by which they are frequented, serve as valuable national gymnasia."

Dr. Morgan might have taken a wider base for his congratulations on the establishment of gymnasia than Oxford and Cambridge; the greater number now of our public schools are also so provided, namely, Uppingham, Radley, Cheltenham, Clifton, Marlborough, and Rugby. We place them here in the order in which they have been carried out, Rugby being our last organisation. From all these schools men are coming up to the Universities, after having continuously, during the most important period of their growing time, received a course of carefully systematised bodily training, carried out in buildings specially designed for this purpose, and conducted by teachers duly prepared, and bearing certificates of qualification. All the youths will bring with them not only chests "larger and deeper," with hearts and lungs stronger, ampler, and more vigorous, but the knowledge of what a good strong, or well-formed chest is, how it is got, and how it may be lost; and this with the similar advantages of the Universities, and shared in by University men, will surely in time enable us to overcome the evil of rowing, the danger to rowing men: for the whole question is now narrowed to one point. Give to men who now take rowing as exclusive exercise such other exercise as will develope the parts of the body which rowing but imperfectly employs, namely the chest, and you at once endow with vigour and strength the parts that are dangerously taxed in the boat-race. We have known men standing 5 ft. 9 in., with chests measuring 32 in. only, rowing in their college eights! And men standing over 6 ft. in their stockings, with chests measuring 35 in., rowing in the inter-University race at Putney! To what end can these lead? to what but danger to the men, alarm to their friends, and injury to the name and to the interests of the art to which they affect to be devoted. We repeat here what we uttered years ago—"No man of ordinary stature and fair growth should be allowed to put hand upon an oar in a racing boat until his chest has the minimum

girth of 36 in.; less will not give him space adequate to the full and fair action of the vital organs within, in the work upon which he would engage; less no man of ordinary stature and fair growth need pass his eighteenth year without possessing."

In bringing these remarks to a close, we desire heartily to congratulate Dr. Morgan on his book, both in conception and execution, and also to congratulate University oarsmen in having a work of this character dedicated to investigations of the doubtful and disputed points of their favourite exercise. If he has not succeeded in showing that the Putney course is quite free from danger, he has shown that it is not so perilous as it was pronounced to be,—*i.e.* not the *via mala* which it had been named. To the disputants on both sides we would say with the peace-loving innkeeper in Silas Marner, "Ye are both right and both wrong; shake hands and be friends."

ARCHIBALD MACLAREN

THE MAMMALIAN SKULL

Zur Morphologie des Säugethier-Schädels, von Joh. Chr. Gustav Lucae. With three lithographic plates and eight woodcuts. (Frankfort, 1872.)

THIS contribution to the anatomy of the Mammalian skull treats chiefly of the comparative proportions of those of Carnivora and Ruminants. After quoting Prof. Huxley's dictum on the importance of making longitudinal sections of every skull in an ethnological museum, the author justly insists upon its applicability to comparative osteology; and begins by a discussion on the true cranio-facial axis. He reviews the definitions adopted by other writers, and describes it as extending fro n the anterior margin of the *F. magnum* to the *F. cæcum*, thus including the basi-occipital, basi-sphenoid, pre-sphenoid, and cribriform plate of the ethmoid bone. He regards it not as a mere imaginary line drawn through the centres of these links in the chain, but as the actual solid elongated mass which they form when the surrounding parts are removed. Hence he speaks of the upper surface of the cranio facial axis, or, as he prefers to call it, the base of the skull, turned towards the brain, and its lower surface turned towards the pharynx and face.

The discrepancies between the different anatomists who have written on this subject have been chiefly due to the different objects for which the structure of the skull has been studied. To the morphologist, guided by a knowledge of embryology and comparative anatomy, it appears monstrous to include the diameter of a foramen as part of the base of the skull, formed of a series of bones which agree in their relations and partly in their development with the centra of the vertebræ. On the other hand the descriptive zoologist, and especially the ethnologist, to whom "transcendental anatomy" is apt to appear harsh and crabbed, asks fairly enough that he may be allowed to fix upon such a base-line as shall give him the most useful and convenient method of comparing the shape of different skulls. And if the practical physician tries as well as he can to ascertain the dimensions of the cranium during life, he is obliged to content himself with the best base-line he can get, which is probably that from the root of the nose to the most hollow part below the occipital protuberance.*

* See an interesting paper by Dr. Gee in the St. Bartholomew Hospital Reports for last year.

Prof. Lucae's object is a morphological comparison between the skulls of man and certain other mammals, and for this purpose we think his cranial basis is well chosen. It agrees with the "cranio-facial axis" adopted by Prof. Flower in his "Osteology of the Mammalia" (pp. 104. 105), in the chief point in which it differs from Huxley's "basi-cranial axis" (Journal of Anat. and Phys., Nov. 1866, p. 67, and "Anatomy of Vertebrated Animals," p. 23), namely, by the inclusion of the mesethmoid bone. And it differs from Prof. Cleland's "base-line" (Phil. Trans., 1869, p. 122), by the exclusion of the foramen magnum, as well as in being an actual mass of bones instead of a line drawn for purposes of measurement.

The most important question is, whether the line ot bones which continues the centre of the vertebræ forward should be considered to stop with the pre-sphenoid or no. Having passed the basi-sphenoid, with which the notochord ends, and admitted the pre-sphenoid into the cranial axis, there seems no good reason from the development, the structure, or the relations of the bones, for not including in the series the next in order. And this must be the mesethmoid: for the claims of the vomer to be considered the centrum of a nasal vertebra may be put aside, because unlike the rest of the axis it is developed from membrane, because it takes no part in supporting the cerebrospinal axis, and because it is not articulated with the frontals or even with the anterior end of the pre-sphenoid.

Having defined the cranial basis, Prof. Lucae proceeds to compare the inclination of its four segments to each other and to a right line joining its two ends. This line, which in man of course will fall *below* the base of the skull, falls *above* it in Carnivora, and more or less completely *in* it in Ungulata. The differences chiefly depend on the greater or less inclination of the brain to the medulla oblongata, and the more or less horizontal position of the face and hence of the olfactory nerves. Careful measurements are given of the dimensions of the segments of the cranial axis and of the angles they make with each other in six Carnivora and eight Ungulata.

Next follows a comparison between the vault of the cranium and the facial bones in the wolf and antelope (*Redunca ellipsiprymna*). The compact osseous structure of the former is contrasted with the more spongy character of the latter; and it is shown how the position of the centre of gravity is altered by the great canine teeth of the carnivora and the horns of ruminants. A short section follows on the changes brought by age; and then come measurements of the cranial angles in various marine Carnivora, in Rodents, in the pig, barbirussa, and *Hyrax*. The last section treats of the skulls of monkeys and of man. Here the cranial axis, which in the seals is somewhat concave above, in otters almost flat, and gradually more bent in Carnivora and in Ruminants, has become strongly convex above, so as to make the cribriform plate and the foramen magnum horizontal instead of vertical, while the length of the vault of the skull in comparison with its base (as above defined) has enormously increased. The remarkable twisting down of the face under the cranium in some Ruminants (for it is little marked in the deer tribe), which is here noticed, has been already well described by Prof. Flower in the work above quoted. It is a remarkable character, but certainly

not enough to warrant us in pushing the Ruminants between the Carnivora and the lower apes.

The woodcuts and lithographic figures of this paper are not very clear, even with the aid of red ink to distinguish the outline of the section of a skull from its profile, when printed together; and there are several printers' errors, e.g., *Hydracherus* for *Hydrochoerus*, and what is more important, *hintre* is put for *mittlere* (p. 27).

Prof. Lucae modestly compares his work to that of a hodman, who has plenty to do when kings build their palaces. These royal castle-builders are of course the more or less adventurous theorists who construct their *Stammbäume* by help of such anatomical details as are here collected. All zoologists, whether, like Lamb's nurse, "wise and wondrous skilled in genealogies," or contented to work out the raw material which is always necessary, will welcome such contributions to osteology as the present, which forms so excellent a continuation of the author's previous labours on *Raçenschädel*, and will hope that they may be still further extended in the same direction. P. H. PYE-SMITH

SYMONDS' RECORDS OF THE ROCKS

Records of the Rocks. Notes on the Geology, Natural History, and Antiquities of North and South Wales, Devon, and Cornwall. By Rev. W. S. Symonds, F.G.S. (London: John Murray.)

MR. SYMONDS is an enthusiast, and one of the best type. In the intervals of his clerical work he is pretty sure to be found either with his hammer among quarries, ravines, and railway cuttings, or exploring some crumbled ruin or mouldered encampment, or lecturing volubly to a hill-side auditory on the rocks beneath their feet, or showing his well-known features at the sectional meetings of the British Association. Such have been his favourite pursuits for some thirty years. In the present volume he gives us jottings from the note-books which record his doings during that long period. The book is not a formal scientific treatise, nor does it follow any definite geographical sub-division in the districts described. An introductory chapter of a somewhat miscellaneous kind is followed by ten others devoted to the various palæozoic formations of Wales and the Southwest of England. But the writer does not confine himself to the geology of the various districts, he has much to say about antiquities and natural history, and says it pleasantly enough. Nor does he restrict his remarks to those parts of the country mentioned in the title-page, for he has been away up even into the wilds of Sutherlandshire, and tells about the rocks there and the alpine plants, and the minerals, and the old glaciers, and how he broke a trusty rod in fishing for salmon there. He makes his way cheerily wherever he goes, and duly chronicles the kindness shown to him. The perfect honesty and candour of the writer are conspicuous throughout. Now and then, however, the delight with which he has seen a fact for himself leads him to write as if nobody had seen it before him. For instance, on p. 91, he tells that "on an expedition two years ago in company with Captain Price, I ascertained that the quartz-rock of Queenaig with its tubes rests unconformably on Cambrian sandstone." A very good observation, Mr. Symonds, but not unknown before you and the Captain were up there.

The illustrations, which are numerous, have been largely taken from Murchison's "Siluria;" but we can specially commend some new engravings from drawings by Sir William Guise—admirable both for their artistic conception and geological truth.

OUR BOOK SHELF

Yarrell's History of British Birds. Revised by Alfred Newton, F.R.S., Professor of Zoology in the University of Cambridge. Part V.

THE improvement which Prof. Newton's excellent edition of Mr. Yarrell's work is undergoing by passing through the hands of its accomplished and assiduous editor, is evident on every page, and the care with which the large mass of literature on the subject of most of the species has been studied, must be evident to all readers. The chief features of this part are the following. The author has entered with considerable detail into the puzzling question of those forms or species of blue-throat, *Ruticilla suecica*, *R. leucocyana* and *R. wolfi*—of which the first only can be said with certainty to have occurred in this country. The so-called "Melodious Willow Wren," of which two examples have been met with in the British Isles, is shown on Mr. Dresser's authority to be the Icterine Warbler (*Hypolais icterina*), and its distinction from the nearly allied Polyglot Warbler (*H. polyglotta*) is carefully pointed out, and it may be mentioned that these two birds have only a superficial resemblance to the true Willow-wrens, among which they have been erroneously placed by most British authors. The evidence as to the occurrence of the Marsh Warbler (*Acrocephalus palustris*) in England is shown to be very defective, and the editor declines admitting it at present to our fauna. The Aquatic Warbler (*A. aquaticus*) on the other hand, seems to have been obtained some three if not four times. The history of that very interesting species Saddler's Warbler (*A. luscinioides*) is fully given, more so than is done in any other work with which we are acquainted. It was doubtless in former days a regular, though never a very abundant summer visitant to the eastern counties of England, until the drainage of the meres and fens unfitted wide districts for its habitation. The first example of the species ever brought to the notice of naturalists was obtained early in the present century by a party of Norfolk observers, including the late Sir William Hooker. This specimen was in 1816 shown to Temminck, then on a visit to London, and by him said to be a variety of the Reed Wren, a bird from which it may be fairly separated generically. Some years after, Savi described it from Italian examples, and it has always had the reputation of being a southern species. But it is to Englishmen that we owe nearly all the information we possess concerning it. Its nest and eggs were discovered near Cambridge in 1845, three years before anything was published about them on the Continent, and its peculiar habits have been chiefly described by Englishmen, from their own observation, whether in this country or abroad. The account of this species has been written *de novo*, and great pains has indeed been taken to bring the history of all the other birds treated in this part (fourteen in number) up to our present state of knowledge of them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Cave-deposits of Borneo

THE following letter from Mr. Everett to myself was accompanied by a plan and section of one of the caves visited by him and partially excavated. The deposits were as follows:

	ft. in.		ft. in.
1. A thin layer of stalagmite.			
2. Black impure guano	0 3	to	1 0
3. White clay with *Potamides decollatus*	1 0	,,	2 6
4. Guano		variable	
5. Débris of clay and guano, with fragments of limestone and stalagmite in abundance...	? 2 0	to	3 0
6. Pure yellow felspathic clay	4 0	,,	5 0
7. Limestone floor.			

This particular cave could not be readily worked owing to the influx of water, but other caves exist at higher levels which would be more promising. The expense for six months' work, according to Mr. Everett's estimate, would not be more than the mere passage-money of anyone going out from England. I may add that Mr. Everett quite understands the proper mode of working, having had personal communication with Mr. Pengelly on the subject at Kent's Cavern. He is now thoroughly familiar with the country and the workmen to be employed, and it seems a great pity that advantage should not be taken of his residence in so interesting a locality, the proper exploration of which may throw light on a variety of biological problems.

ALFRED R. WALLACE

"You will recollect that some three years ago I came to Sarawak with the object of making general collections of natural history and, more particularly, of investigating the cave-deposits of Borneo.

"From time to time I made excavations in various caves situated in Upper Sarawak, being assisted pecuniarily by the Rajah to a certain extent. These excavations varied in depth from 4 ft. to 14 ft., and were made in different situations in the caves. No remains of interest, however, were discovered beyond some teeth of a Hystrix, and bones of man, bats, geckoes, &c., in the most superficial deposits, and the only result worth recording was the find of a stone axe-head in a bed of river-gravel. This celt was forwarded to Sir C. Lyell, and such remains as were obtained from the caves were sent to Messrs. Busk and Pengelly at intervals; but the latter, together with a recent tooth of Rhinoceros and two collections of miscellaneous specimens, appear to have been wrongly transhipped in Singapore, and I have never been able to trace their whereabouts.

"After considerable observation and experience I now wish to state with all frankness my belief that my work was not carried on as it should have been, and that the non-existence of ossiferous deposits in the Bornean caverns is very far from being a proven fact. The inquiry as conducted by myself was not *thorough*, and it was unsatisfactory partly because I was in serious pecuniary difficulties myself, and partly because what I saw of the poverty of the Government and the remarks I heard dropped about the folly of expending money on such objects made me very shy of taxing the Rajah's liberality. I was, and am still, persuaded that the expense of cave-working in a country like this would have proved very much heavier than the Rajah had any idea of, and hence I worked with inadequate support.

"In the event of those who are interested in the exploration being desirous of having it continued, I venture to suggest that the person chosen for the work must either possess considerable private means or he must be employed at a regular salary; and further, that the work should be carried on with sufficient funds to render it independent of any assistance the Government here might afford. Money is so scarce here, and public wants so many and pressing, that assistance for purely scientific objects is not to be expected. Coolies are not procurable now under a wage of 2*l.* a month, and, owing to the rivers being the only roads, travelling expenses are heavy. For tools, lights, gunpowder for blasting, and such preliminary expenses, a sum of 15*l.* would be sufficient; and the monthly working expenses would vary from 10*l.* to perhaps as much as 15*l.*, according to the accessibility of the cave to be explored; so that for working a cave for three months a sum of 65*l.* would probably be required.

"As I am now employed in the Government service, I do not think I could undertake the work unless a formal application was made to the Rajah for the necessary leave of absence. Even were leave obtained, I do not suppose that I should continue on Government pay, and I could not afford to undertake the work under a salary of 25*l.* per month. The cheapest way of conducting the exploration would be to send out a gentleman of independent means who would do the work for its own sake, and then only the actual working expenses need be subscribed for. Supposing remains were ultimately found, the item of freight would have to be added to the working expenses.

"I am induced to write you this letter from reading a note in NATURE for June 13, 1872, with regard to the Victoria caves, in which two years of constant but seemingly fruitless work has in the end proved successful. Trusting that another exploration may be attempted in this far more important field, and with like success, I remain, &c., "A. EVERETT

"To A. R. Wallace,

"Sarawak, February 1, 1873"

A Fact for Mr. Darwin

THE interesting fact contained in the following passage appears to me to deserve disinterment from the pages of a very large book, a work too, which, so far as I know, has never been translated. It occurs in the "Erpétologie Générale" (Par Duméril et Bibron, tome vi. p. 467), and I met with it while employed in working out a collection of reptiles, which I was engaged in classifying. The passage is as follows:—"Dans les villes d'Égypte, on rencontre souvent des charlatans exposant à la curiosité publique des Eryx javelots vivants auxquels, afin de les faire passer pour des Cérastes, ils ont eu le soin d'implanter, en manière de corne, audessus de chaque œil, un ongle d'oiseau ou de petit mammifère, par le même procédé que celui qu'on emploie dans nos fermes pour fixer deux ergots sur la crête de certains coqs quand on les chaponne.

"C'est d'après des individus ayant la tête ainsi armée de deux fausses cornes, qu'Hasselquist a fait son Anguis cerastes. Nous avons dans les collections du muséum des individus dont la tête porte ainsi des ongles recourbés d'oiseau, avec leur cheville osseuse, dont l'adhérence à la peau est parfaite."

Here is a fact, not only well authenticated, but capable of verification, demonstrating such close affinity of intimate structure and function between animals of *different classes*, that the skin appendage of one has been actually engrafted upon the skin of the other; the claw of a bird has formed perfect union with the skin of a snake. A good illustration of the affinity between birds and reptiles pointed out by Prof. Huxley.

I do not notice that statement about the claw of a small mammal being used for this purpose, because specimens illustrating it are not referred to.

The snakes alluded to in the passage are the *Eryx Jaculus* (one of the Erycidæ or sand-snakes of Dr. Günther), which is perfectly harmless: and the *Cerastes Hasselquistii*, a small but fierce and venomous viper; both inhabiting Egypt, and the latter supposed to have been the "asp" of Cleopatra. The Cerastes obtains its name from the so-called "horns," peculiar to the males, which are developed from modified scales over the centre of each orbit, attaining the length of about half an inch. The Eryx is about the same size as the Cerastes, for which it is passed off by the Egyptian snake-charmers, when manufactured as above described. H. D. MASSY

Grenada Villas, Netley, near Southampton

The Phœnician Vademecum

IT is gratifying to see (vol. vii. p. 351) that you express a doubt whether the Cowrie shells in the Pomeranian barrows must necessarily, as Wagner supposes, have been brought by the Phœnicians. Because the earliest Greek historians introduced the Phœnicians to us they have been employed as a universal machinery for carrying out all kinds of operations. This theory is in fact incompatible with our present knowledge of the duration of the human race, and, we may say, with the relative antiquity of the Phœnician epoch, which can date but little beyond the historic period. Thus we are led to neglect the evidences of skulls, weapons, tools, monuments, and languages, which show that there must have been communications between distant regions long before the rise of the Phœnicians. There are many prehistoric races which had a sufficiently wide distribution to provide for the dissemination of such a small object as the Cowrie. Among these may be named the dwarf or short races, of which the Mincopies of the Andamans are a type; the race now represented by the Agavs of the Nile, Avkhass of Caucasus (Achivi), and Omagua and Guarani of Brazil; and the Dravidian race. Populations which could distribute men over the continents and islands of Europe, Africa, Australia, and the Americas must have been capable of distributing cowries and beads without Phœnician intervention. At present the Phœ-

nicians are blocking the road to prehistoric research, as the Hebrews formerly did. HYDE CLARKE

32, St. George's Square, S.W.

Earthquake Waves

THE observations at p. 385, on the operation of self-resisting tide-gauges of the U. S. Coast Survey, in illustrating the phenomena of earthquake waves, suggest the expediency of the same means being adopted in the basin of the Mediterranean. This could possibly, by a little correspondence and agitation, be effected at Naples, Athens, Constantinople, and Alexandria. The Turkish and Egyptian Governments are very likely to listen to any representations on behalf of the cause of science. Although the Mediterranean is considered tideless, there is a daily fluctuation of two feet in parts of the Levant, but what is material is that earthquake waves are known to have been manifested at Smyrna.

If our Government could be induced to encourage observations at Gibraltar and Malta, we should obtain a combination of points of contact for two allied regions.

HYDE CLARKE

Spectrum of Aurora

I WISH to make a correction with reference to my observations on the spectrum of the aurora, as given by J. R. Capron on p. 182; for he has credited them with greater accuracy than they profess to have: I have no doubt that my line No. 5, seen at wave-length 500 or 510, is the same as Lord Lindsay's and Elger's No. 4, and probably as Procter's. This is the more likely, seeing that the two former placed the principal line much nearer the red end than I did; for I assumed Angström's position (5567) to be correct. This leaves but one observer of No. 5 (Barker), and possibly his line also is the same; in that case his No. 4 will be the same as Lord Lindsay's No. 3.

I have seen published the following determinations of the positions of the auroral lines, in addition to those J. R. C. has given:—

	Wave-length.
No. 1. R. J. Ellery	635
No. 2. O. Struve	5545
Angström	5567
German North Polar expedition	5569
Peirce (as reported by Winlock)	557
Respighi	5573
R. J. Ellery	560

No. 3. Peirce has two lines near here—5315 and 5205; the latter is probably Lord Lindsay's "line near E," and possibly A. Clark, Jun.'s line also.

	Wave-length.
No. 6. Peirce	464
No. 7. Peirce	431

Peirce also gives lines at 545 and 486.

My latest determinations from my own observations are as follows:—

	Wave-length.
No. 1.	606
,, 2.	566
,, 3.	5165
,, 4	5015
,, 6.	4625
,, 7.	4305

I have never seen a line at 532 again.

As to the continuous spectrum, it reaches from No. 2 to No. 7, being brightest from a little beyond No. 2 to No. 6. This part of the spectrum does not give me so much the idea of a true "continuous spectrum broken up by dark bands," as of a series of bright bands too close to be distinguished.

Sunderland T. W. BACKHOUSE

Spectrum of Nitrogen

IN a paper communicated to the Royal Society by Mr. Arthur Schuster, it is stated that the line spectrum of nitrogen may be obtained under all pressures and temperatures if every trace of oxygen be removed by heating sodium in the vacuum tube.

I should be glad to learn whether any of your readers have successfully treated Mr. Schuster's experiments.

My friend, Mr. Lee, and myself have, on several occasions, attempted to do so, but always without success.

On heating the sodium we invariably find that an increase of pressure takes place from the liberation of hydrogen which, although very greatly lessened, is not entirely removed by drying the gas with sulphuric acid. On again exhausting we obtain, with the simple current, a spectrum of lines, not of nitrogen, but, in every instance, those of the second so-called hydrogen spectrum first described by Plucker, and afterwards noticed by Wullner and Angström.

This spectrum disappears as soon as the Leyden jar is used, and only the ordinary hydrogen spectrum is then visible.

The only effect which the sodium appears to produce is the liberation of hydrogen; for the same line spectrum can be obtained by exhausting a tube filled with hydrogen, or even with unpurified atmospheric air.

I was struck by the fact that only a few of the lines given by Mr. Schuster in his table of wave-lengths coincide with those of the known spectrum of nitrogen, while many of its most brilliant lines, including that which is its chief characteristic, the double green line (wave-length 5005-5002, Thalen) are not represented in his spectrum.

That the line spectrum of nitrogen can be obtained at all pressures, has been shown in a paper by Mr. Lee and myself, which has been sent elsewhere for publication; but that it can be obtained at all temperatures, by which, I presume, Mr. Schuster means either with or without the Leyden jar, is certainly contrary to our experience.

Instinct

The Heredity of Instincts

THE following may perhaps serve as a contribution to the question so much discussed of late concerning the transmission or acquirement of likes and dislikes amongst the lower animals. It is an extract from a letter of a brother of mine, an officer in India:—

"I have at present a little tiger-cub, about the size of a spaniel, a most interesting pet, though it will soon be a dangerous one. He made friends at once with my fox-hound puppies, and romps with them incessantly. When he sees a cow or a goat his real nature betrays itself. He has no fear whatever of any dog; *but, strange to say, is thrown into a paroxysm of terror at the sight of a kitten or a tiger-skin.*"

This hardly seems to bear out the assumption so commonly made, that manifestations of this kind must have a history in the experiences if not of the animal itself, at least of its ancestors. We can hardly suppose the parents of this cub to have adopted a frame of mind respecting the race of tigers equivalent to misanthropy amongst ourselves, and the experience of cats or kittens must be small indeed in the jungles of the Decan.

St. Asaph, N. Wales J. G.

Sense of Direction

IN Mr. Darwin's article in NATURE for last week there is a passage about "the sense of direction being sometimes suddenly disarranged," that brought to my mind assertions I had frequently heard made when travelling some years back in the wild parts of the State of Western Virginia. It is said that even the most experienced hunters of the forest-covered mountains in that unsettled region are liable to a kind of seizure; that they may "lose their head" all at once, and become convinced that they are going in quite the contrary direction to what they had intended, and that no reasoning nor pointing out of landmarks by their companions, nor observations of the position of the sun, can overcome this feeling; it is accompanied by great nervousness and a general sense of dismay and "upset;" the nervousness comes after the seizure, and is not the cause of it. I was present in a company of hunters when a tale of this "getting turned round" was told as a good joke against one of the party—a Nimrod of renown—the leading features of which he was reluctantly obliged to confess to the truth of, while denying some minor points that had been added to embellish it, as making him more ridiculous than he was: it would take up too much of your space to tell the particulars of the story. The feeling is described as sometimes ceasing suddenly, and sometimes wearing away gradually. Would it not be strange if it should appear that there is a "sense of direction" other than an acquired sense of

direction the result of unconscious observation, and that some animals possessed the first in a pre-eminent degree? The wonderful faculty hunters possess of finding their way through immense mountainous tracts so thickly wooded that one cannot see farther than a few yards at a time, may perhaps be accounted for by this power of unconscious observation alone; but is it so easy to account for a sudden derangement of the sense of direction, and the peculiar distress it occasions, even when there is no ground for alarm on the score of safety? This appears a kind of converse of the instance Mr. Darwin gives of the case of old persons losing their way. HENRY FORDE

The Walk, Lyme Regis, April 6

Destruction of Rare Birds: White Tom Cats

MANY of our birds are now protected by law, at certain seasons of the year. But unhappily rare visitants are mercilessly killed. Last year a pair of Hoopoes frequented my grounds both in the spring and autumn. It was a great pleasure to see this bird (of which Horapollo wrote that it was worthy to be "the sceptre of the gods on account of its gratitude"), on the lawn, busily searching for insects, or alighting on the surrounding trees. Every lover of nature will sympathise with my household and myself, in our distress that they have been shot; not even for the miserable satisfaction of the mere collector, but far worse, that their plumage might be stuck on a lady's head-gear. To shoot storks, spoonbills, bee-eaters, hoopoes, &c., which might be regular visitants and nest here, is a very different thing from securing chance arrivals from remote regions, which could never be naturalised in England.

One of your correspondents wrote recently of the deafness of white Persian tom cats. I possessed such an one for years which was not deaf; another, in a house near me, is not deaf, and I now have a grand fellow, a true Persian, in possession of all his faculties. A neighbour's pussy having walked into the house, with characteristic Oriental hospitality he went to the larder, and selecting a fish which he doubtless thought would be a *bonne bouche* for his guest, laid it before his friend, and did not himself partake of it.

Trebah, Cornwall, March 31 C. F.

Phosphorescence in Wood

IF some one would be good enough to give me a little information concerning the following (to me novel) phenomenon, he would oblige.

A heap of sticks intended for firing, lay in a corner of our boiler-house, and among them were some round pieces of Scotch fir (*Pinus sylvestris*) about 6 or 8 inches in diameter, and 18 inches long. These had been sawn from a pole which had lain out in the wet, and being consequently rather damp, the cut portions were placed in the warm boiler-house to dry. The blocks I speak of appeared quite sound. From the circumference of three or four of them the bark was rubbed off, here and there in patches, and a few chips were broken away from the edges. The fresh surface beneath was covered with a thin layer of the ordinary sticky resin, which so copiously exudes from this and other trees. When it was dark the steward happened to enter the boiler-house, and looking towards the sticks he was surprised to see a pale steady light emitted by some of them. At first he thought it was the reflection of the moon which shone through the window. Closer examination, however, proved: (1) that the moon did not shine on the sticks at all; (2) that the sticks were self-luminous; (3) that it was only the Scotch fir blocks which emitted any light; (4) that the light was confined to the resinous surface, exposed beneath the bark and chips; (5) that the surface beneath the chips (that is where more than the bark had been removed) was brightest. The steward carried the block which appeared most brilliant to an outhouse, where it still continued to "shine." He then broke off some small loose chips with his fingers from this block, and each separate chip sent forth the same steady pale light. My informant states that the phenomenon was very "curious." Perhaps this species of phosphorescence may not be unusual after all; but not being well "up" in the subject, I would with your permission, sir, merely ask is it common, and if so, how is it explained in the instance I mention? I may state that the steward gave me all the information. I saw the blocks afterwards but not the curiosity. RICHARD M. BARRINGTON

Indices of Journals

PUBLISHERS of periodicals, scientific or other, issue general indices only after intervals of ten or twenty years. In the ninth or nineteenth year the investigator of bibliography has to turn over every volume, a fearful waste of time. I have consulted with the librarian of this University, and the proposal we have to make is that the publishers should send, at least to the libraries, a duplicate copy of the annual index of each journal, or better a revised proof in slips, to be cut up and pasted into a volume which would thus be annually extended for nine years, and superseded in the tenth by the general index. The addition to the expense in a library is very trifling, and a small payment for the extra copies of the indices would protect the publishers against loss.

Glasgow University JOHN YOUNG

THE DUTCH SOCIETY OF SCIENCES

THE following account of the history of the Dutch Society of Sciences at Harlem has been drawn up by the Secretary, E. H. von Baumhauer, for publication in England. It shows the progress of science in Holland, and the great interest taken in its advancement both in that country and abroad, as proved by the award of so many valuable gold medals, and by the recent establishment of a central bureau for the exchange and transmission of books; all which activity is maintained without any of the expense falling on the scientific members.

In the middle of the last century the greater part of the aristocracy of Harlem were desirous of finding recreation in physical experiments and scientific researches. Along with several regents of the town they decided in 1752 to establish a self-supporting society, for the collection of written essays, and the bestowal of prizes on those of meritorious character. At the first meeting, May 21, 1752, the preacher, C. C. H. van der Aa, was appointed secretary, and many other protectors of the sciences and learned men in other parts of the country, were invited to become members, amongst whom were Musschenbrock, Gambius, Alberti, and others, so that by the end of the year the Society was already formed of twenty-three directors and members. The design was to include all branches of science, and to search for everything necessary for the present and future prosperity of the Republic, both in its internal and external relations, in peace and in war. Even communications on theological subjects were not excluded, treated in such a manner as not to offend Christians of any sect. The motto of the Society was *Deo et Patriæ*. By the help of many wealthy persons the Society was enabled to crown several prize essays, published in the transactions. In July 1754 the protectorate was conferred on the young hereditary governor, William Prince of Orange.

Several very eminent native and foreign men became members of the Society, and the first volume of the Transactions was so favourably received that a second edition was necessary. It was also in great part translated into German. The prize questions excited much interest in other countries, so that several were answered by foreigners. Since 1772 an annual programme has been published in both Dutch and French.

After an existence of twenty-five years the Society founded a sub-division, more specially devoted to commerce, agriculture, and industry, under the name of the Commercial Branch. This was the origin of what was afterwards called the Dutch Society for the Promotion of Industry, which in 1877 will celebrate its centenary festival.

The parent institution continued in a flourishing state until 1780; but the mournful political situation of the country for some time after that had a most injurious effect, so that the very name of this Society was continually changed. From 1798 it was called the Bavarian Society. King Louis called himself perpetual President of the Royal Society of Sciences; but in 1820, by order of the Emperor's Governor, the Prince of Plaisance, the name of the Dutch was again adopted, and has been re-

tained till now. William I. willingly accepted the protectorate, and his example has been followed by his successors.

The Secretary Van der Aa, who had been the soul of the Society from 1751 to 1794, was succeeded by the renowned Physical Professor Martinus van Marum, who at his death in 1837 was succeeded by the Professor of Geology, T. G. S. van Breda, who took his dismissal in 1864, when the Professor of Chemistry, E. H. von Baumhauer, was appointed to the office.

From 1754 to 1793 the Society published thirty volumes of Transactions, of which registers by the celebrated T. T. Martinet were issued in 1773 and 1793. These Transactions contain essays on all branches of science, and also many on theology. It was principally through the influence of Van Marum that since then a more predominating share has been taken by physical subjects. From 1799 to 1844 a first series of 24 volumes in octavo, and from 1841 to 1866 a second series of 25 volumes in quarto, and since 1870 a third series of "Physical Transactions" have been published by the Society. In 1802 a volume in octavo of "Mechanical and Mathematical Transactions" was published, and in 1821 and 1822 two volumes in octavo of "Philosophical Transactions." From 1815 to 1820 three volumes in octavo on literary and archæological subjects, and since 1851 2 volumes of "Historical and Literary Transactions" in quarto have been published. The second and third series of "Physical Transactions" are especially distinguished by the memoirs written by the most eminent men in Europe, mostly illustrated by excellent plates.

The revenue of the Society is derived from the interest of capital, for which it is indebted to the kindness of the directors and from the annual subscriptions of the actual directors. It receives no pecuniary assistance whatever from the Government.

With these means the Society endeavours to make known to the world excellent writings on physical subjects, which otherwise would be published with difficulty on account of their special character and the costliness of the illustrations.

Besides supporting such works, the Society encourages scientific researches, and since 1866 has published a journal in the French language, edited by the Secretary, under the title of "Archives Néerlandaises des Sciences Exactes et Naturelles." of which already 7 volumes have appeared. This journal is destined to make known to the world all that is produced in the Netherlands and the Dutch possessions related to physical science. This is of great service to the Dutch scientific men, since their researches, being for the most part written in a language so little known generally as the Dutch, would otherwise obtain only a very partial publicity.

The Society is composed of an indefinite number of directors, for the greater part gentlemen of wealth and social importance, who pay an annual contribution of fifty gulden (about four guineas) and manage the finances, which, however, now are especially under the charge of five directors living in Harlem, presided over by the president. There are also sixty native and sixty foreign members, who are chosen in the General Assembly, held on the third Saturday of May, from a list of candidates made by the directors and members. These members pay no contribution whatever, and receive free all the publications of the Society. This membership of the oldest and most important Dutch society is esteemed a great distinction by learned men. The English members are Davidson, Davis, Kirkman, Hooker, Lyell, Owen, Sorby, Tyndall, and Wheatstone. The president of the Society is chosen every three years by the directors. At the present time the office is filled by Baron F. W. van Styrum. When a vacancy occurs in the secretaryship, the native members nominate six from amongst themselves from whom the secretary is chosen by the directors. He also acts as treasurer and librarian, and is the only paid officer, living in Harlem in the magnificent building belonging to the Society.

The Society exchanges its publications with almost all the foreign academies and learned institutions, and to facilitate the interchange of books, the Secretary has instituted a central bureau in imitation of the American Smithsonian Institute.

As already named, the Society has regularly published a list of prize questions, the meritorious answering of which is rewarded by a gold medal of the value of about twelve guineas, to which may be added an equal sum or more, in money. At the present time no less than twenty such medals and prizes are offered for an equal number of subjects.

At the centennial festival in 1852 the Society offered a prize of 1000 gulden for the most important work in one of the branches of physics, which should be published during the next four years, and a second of 2,000 gulden for the best in four following years. In the General Assembly of 1857 it was decided that this latter prize should not be bestowed upon anyone, but that M. Foucault should be informed that the Society regretted that his communicated discoveries had not happened in the specified time, but would bestow on him the gold medal as a proof of the high value placed on his researches. On the contrary, the first prize was doubled, on account of the difficulty of deciding between two authors of transmitted works, M. A. Decandolle of Geneva, and Herr O. Heer of Zurich, who were both judged to be deserving of the 1,000 gulden offered to each.

In the general assembly of 1869 the Society resolved that quite independently of the medals bestowed on crowned prize questions, two new medals should be established, of the intrinsic value of 500 gulden (about 40 guineas), one to bear the name and image of Huygens, and the other those of Boerhaave. These medals will be bestowed alternately every two years on learned men in the country or abroad, who shall be thought by the Society to have made themselves particularly meritorious during the last twenty years in a fixed subdivision of the mathematical and physical sciences, by their researches, discoveries, or inventions. The Huygens medal was to be assigned in 1870 to the branch of physics, and will be assigned in 1874 to chemistry, in 1878 to astronomy, in 1882 to meteorology, and in 1886 to pure and applied mathematics.

The Boerhaave medal was to be assigned in 1872 to geology and mineralogy, and will be assigned in 1878 to botany, in 1880 to zoology, in 1884 to physiology, and in 1888 to anthropology; after which the same order will be repeated over and over again in the case of both medals, so that one medal will be given every twenty years for each of ten different subjects. The judgment is to take place by a Commission to be appointed by the directors, of which Commission the Secretary of the Society is always to be a member. The award is to be made in the General Assembly, in accordance with the pre-advice of the Commission, accompanied with a particular account of the motives which have led to the choice.

The first Huygens medal was awarded in 1870 to Rodolph Julius Emmanuel Clausius, Professor at the University of Bonn, as founder of the mechanical theory of heat; and in 1872 the first Boerhaave medal was given to Henry Clifton Sorby of Sheffield, for having made himself particularly meritorious by his microscopical researches in connection with geology and mineralogy, during the last twenty years.

The portrait of Huygens was taken from a copper-plate engraving by Edelink, and that of Boerhaave, from an oil painting by Troost, now in the Academy at Leiden. Independent of their size (3 in. in diameter, 9 oz. troy) both these medals are most creditable to all parties concerned as fine works of art.

ON THE SPECTROSCOPE AND ITS APPLICATIONS

VII.

ANOTHER point was also very obvious to those who are familiar with these inquiries, namely, that if these prominences really consisted of gas, by the use of a powerful spectroscope it was perfectly unnecessary to wait for eclipses at all. The reason for this will be clear on a little consideration; if we take a continuous or unbroken spectrum and apply successively a number of prisms, the spectrum will become proportionately lengthened, and therefore more and more feeble, and in fact we can thus reduce the light to any degree required; if now, on the other hand, we take a spectrum which consists only of bright lines, say of one line in the red and another in the blue, and as before apply successively a number of prisms, we shall, it is true, increase the length of the spectrum, that is the distance between the two lines, but this will be all; the additional prisms have no power to alter the width of the lines themselves, for we have seen that these are simply the images of the slit, Their light, therefore, will only be slightly enfeebled. owing to reflection merely. Thus if we have a mixed light to analyse, part of which comes from a source giving out a continuous spectrum, and the rest that of a glowing gas, although when working with a single prism no lines may be visible on account of the brightness of the continuous spectrum, yet by using say five or seven prisms we can so dilute the continuous spectrum as to render the bright lines of the glowing gas clearly visible. The case of the red flames round the sun is a case in point. They are invisible to the naked eye and in telescopes on account of the intensely illuminated atmosphere which also prevents anything like bright lines being observed from these red flames, until the bright continuous spectrum has been much reduced, when this has been done the bright lines of the spectrum, should there be any, will appear on a comparatively dark background. M. Janssen, who was sent out by the French Government to observe the eclipse which was visible in India in 1868, Major Tennant, and others, had no difficulty in recognizing in a moment, when the sun was eclipsed, that these things really did consist of gases or vapours, and M. Janssen, a very careful observer, had no difficulty in determining that the gas in question was really hydrogen gas. M. Janssen and myself were also enabled to determine this by observations on the uneclipsed sun, by means of the new method I have just sketched out. The accompanying woodcut (Fig. 40) shows the spectrum which is observed from these solar prominences. The spectrum of the prominences is shown in the upper, and that of the sun in the lower half of the engraving. This method is very easy to understand if you bear in mind the engraving of the spectroscope for solar work, and recollect that when we wish to examine the regions round the sun, the light of the sun is allowed to fall on the slit in such a way that one half of the slit at the focus of the object glass of the large telescope is occupied by the brilliant image of the sun, and the other half is fishing, so to speak, around the limb or edge of the sun, so that if there is anything at all around the limb, the spectroscope, in the—to the eye—unoccupied part outside the image, picks up this something, and gives us its light sorted out into its proper bright lines in the spectrum. This spectrum shows that there is first a bright line, Fig. 41, in

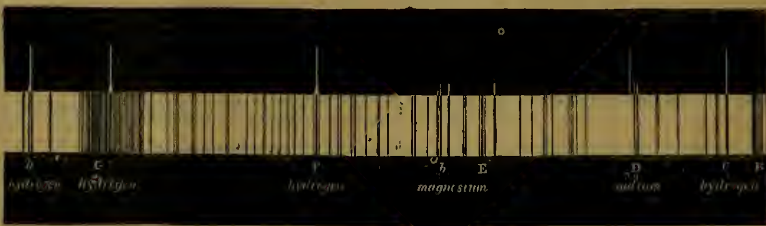

FIG. 40.—Spectrum of the Sun's Photosphere (below) and Chromosphere (above).

FIG. 41 – C line bright in chromosphere, dark in sun.

FIG. 42.—F line in chromosphere, showing widening near the sun.

the red, marked C, which is absolutely coincident with a prominent dark line in the solar spectrum. Now this is a black line which, by repeated observations, we know corresponds in degree of refrangibility exactly with one of the lines given out by glowing hydrogen, when examined in one of these tubes with the electric spark. When, therefore, we get any substance around the sun reporting its light to us, it is perfectly obvious, I think, that if the bright line really be coincident with this dark line, that something is probably hydrogen. This was one of the first lines determined by M. Janssen in the eclipse of 1868. There is another bright line absolutely coincident with a dark line known to correspond in refrangibility with another line given out by hydrogen in the green part of the spectrum, marked F in the figure. This, then, is further proof in favour of hydrogen; and now notice a great difference between the shape of this line and the red line which I drew your attention to just now. An enlarged representation of this line is shown in Fig. 42.

You will bear in mind what I told you about the effect of pressure in altering the spectrum of hydrogen, and that one of the most obvious effects of increased pressure was to increase the thickness of what is called the F line—the line now under consideration, you will see here that the widening of the F line, the green line of hydrogen, really indicates a thickening due to pressure. In that way we have been able to determine approximately the pressure of these circum-solar regions which the spectroscope has determined to be occupied by an envelope of hydrogen gas, mingled sometimes with other vapours, which envelope I have termed the chromosphere. When the pressure of the chromosphere is completely determined, we shall be probably enabled to determine the temperature of the sun.

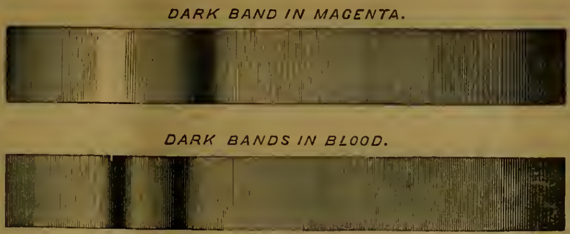

FIG. 43

A line again in the violet corresponds with a dark line in the solar spectrum, which is coincident with a third line of glowing hydrogen which we have before spoken about, and there is still another coincident line. A line in the yellow of the spectrum will also be noticed. This is one which has caused a great deal of discussion, for it is not coincident with any line of any known terrestrial substance. A number of short lines are also shown in the engraving which will be seen to correspond to the part of the chromosphere which is denser, for then the F line of hydrogen has become broad where these lines are seen; these lines show that in the layers of the chromosphere nearest to the sun a number of other substances exist, amongst which may be mentioned magnesium, iron, and sodium. The reason that bodies do not reach up so far from the body of the sun is that their vapours are very much heavier than the gas hydrogen, which is the lightest terrestrial substance known. Such are a few of the practical applications of the spectroscope as applied to the radiation of light. There are other classes of facts relating to the absorption of light, on the consideration of which we shall now enter.

The subject with which we have just been dealing is the radiation or giving out of light by bodies in different states—that is to say, by solid or liquid bodies, or gaseous or vaporous ones. We have now to deal with the action of the prism upon light under some new conditions—conditions which I purposely withheld from you in the last lecture. Light is not only given out, or *radiated*, but it may be stopped or *absorbed* in its passage from the light-source to our eye, if we interpose in the path of the beam certain more or less perfectly transparent substances, be they solids, liquids, gases, or vapours. I will recall one or two of the experiments which have been already described in order that you may see exactly how the perfectly distinct classes of phenomena due to radiation and absorption really run together. You will recollect that I pointed out to you that radiation, or the giving out of light, might be continuous or might be selective, and I am anxious now to show you that radiation is exactly equalled by absorption in this matter; that absorption may also be continuous or selective. We have before taken as an instance of continuous radiation a continuous spectrum obtained by using the electric lamp or a lime-light; that is to say, an example of the general radiation which you get from an incandescent solid—the carbon points of which the poles

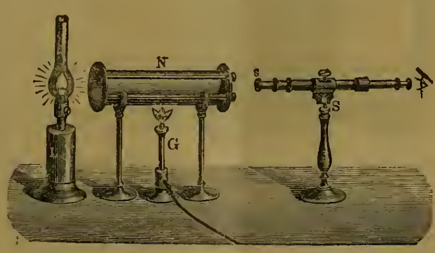

FIG. 44.—Method of observing the absorption of a vapour.

of the lamp are composed, or the solid lime. You will remember that if we take the spectrum of a vapour—as, for instance, that of strontium or thallium—we find that the continuous spectrum is altogether changed, and that in the place of that beautiful rainbow band, continuous from the red end of the spectrum to the violet, we really only get lines here and there, which are due to the selective radiation, and opposed to the general radiation which we spoke of in the continuous spectrum just now. I might have chosen other substances besides strontium and thallium, but I mentioned the spectra of these substances when we were considering the question of radia-

tion. What I have to dwell on now is, that the absorption or sifting of light by different bodies is very like radiation in its results—that is to say, in some cases we have an absorption which deals equally with every part of the spectrum, and in other cases we have absorption which only picks out a particular part of the spectrum here and there to act upon. But there is one important point to be borne in mind; when dealing with absorption we must always have a continuous spectrum to act upon. If we had a discontinuous spectrum to act upon, the thing would not be at all so clear. Having this continuous spectrum, the problem is, what the action of the different substances on the light will be. Let me give you an instance of general absorption. If we take the continuous spectrum above referred to, and interpose a piece of smoked glass, or better, a piece of neutral-tint glass, you will find that the substance will cut off the light and deaden the spectrum, so to speak, throughout its whole length. This neutral-tinted glass, then, has the faculty evidently of keeping back the light, red, yellow, blue, green, violet, and so on; and is an instance of general absorption. A very dense vapour would furnish us with another similar instance. Now, instead of using the neutral-tint glass, we will introduce a piece of coloured glass, the action of which, instead of being general throughout the spectrum, will be limited to a particular part of it. I have now interposed a piece of red glass, which cuts off nearly all the light except the red; and now I interpose a piece of blue glass, which cuts off everything except the extreme violet. By introducing both these pieces in the beam, the spectrum is entirely obliterated.

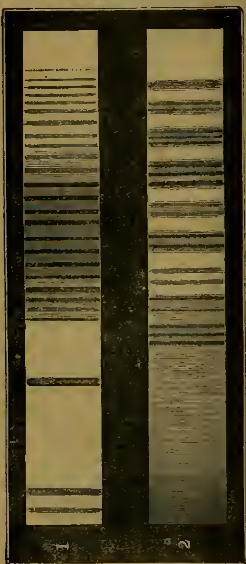

FIG 45.—Absorption spectra of iodine and nitrous fumes.

In these latter cases we have instances, not of general, but of selective absorption, one substance cutting off everything but the red, and the other cutting off everything but the violet. Now the fact that we can absorb any definite part of the spectrum by properly tinted glasses provides us with a practical application of spectrum analysis in the manufacture of the coloured glass used for lighthouses or signals. Further, if astronomers could find a glass of a certain red, or a glass of a certain green colour, we should be able to see the solar prominences every day without a spectroscope.

The first practical application which springs out of these phenomena of absorption is this, that as different substances are known by the effects which they produce on radiation, so also chemists find it perfectly easy to detect different substances by means of their absorption; for instance, the absorption spectrum of nitrous fumes can be shown by taking first our continuous spectrum, which we must always have to start with, and introducing some nitric peroxide between the source of light and the prism. The nitric oxide, immediately it comes in contact with the air, produces dense red fumes, and numbers of fine black lines will be seen immediately crossing the spectrum at right angles to its length, and to a certain extent resembling the solar spectrum with its Fraunhofer lines. Iodine is another substance which gives a coloured vapour, the absorption spectrum of which is very definite and well defined. Fig. 45, Spectrum No. 1, shows the absorption spectrum of iodine vapour, and No. 2 that of nitrous fumes. We are not limited to these substances; we will try something else—blood, for instance, about which I shall have something more to say presently. We shall find that the action of blood upon the light is perfectly distinct from the action of those fumes which we have spoken of; and instead of having typical lines in the green and blue parts of the spectrum, we have two very obvious lines in the more luminous part of the spectrum. The colour of a solution of blood is not unlike the colour of a solution of magenta; but if, instead of using a solution of blood, we use a solution of magenta, we should have only a single black band. The absorption spectrum of potassic permanganate solution is another beautiful instance. We have here something totally unlike anything we had before. Instead of the two dark bands which we saw in the case of the blood, or the single band in the case of magenta, we have four very definite absorption bands in the green part of the spectrum. So that you see the means of research spectrum analysis affords as far as regards radiation, is entirely reproduced in the case of absorption, and it is perfectly easy, by means of the absorption of different vapours and different substances held in solution, to determine not only what the absorbers really are, but to determine the presence of an extremely small quantity. Further, by allowing the light to pass through a greater thickness of the absorbing substance, the absorption lines are thickened and new regions of absorption are observed. This fact was discovered by Dr. Gladstone, who used hollow prisms containing the substance.

J. N. LOCKYER

(*To be continued.*)

PROFESSOR ZOLLNER ON THE CONNECTION BETWEEN COMETS AND METEORS

PROFESSOR F. ZÖLLNER alludes in the commencement of his paper read before the members of the "Kön. Sächs., Gesellschaft der Wissenschaften" to the epoch which Schiaparelli's discovery of the concordance of the orbits of some small comets with those of periodically returning showers of shooting stars has made in the astronomical world. He quotes an instance in proof of this, namely, Biela's Comet. On November 27, last year, the earth was crossing the exact spot in her orbit, which had been cut by Biela's Comet two and a half months before. Observers aware of the coming event were on the alert with their instruments, but no good results were obtained owing to the unfavourableness of the weather.

From these facts, he says, we must naturally conclude that the physical constitution of these bodies is the same, and we are strengthened in our conclusions by Schiaparelli's discovery of the identity of the envelopes and tails of comets with clouds of meteors seen by reflected sunlight, the separate elements of which only become visible at a shorter distance.

Observations, however, with the spectroscope, contradict this assumption; the light given out by comets. is found not to correspond with that of the sun; it is a light peculiar to them, like that of a glowing gas.

Further on he quotes Schiaparelli's own words to some length, with respect to the attraction exercised by other bodies on the matter composing the nuclei of comets,

which is drawn from them in directions other than that of their orbits. Schiaparelli maintains most distinctly that the tails of comets and meteoric aggregates are not identical.

Professor Zöllner points out that if we are not to suppose that the physical constitution of both phenomena is the same, there only remains their identity of origin as an explanation of the remarkable coincidence of these bodies in space. Pursuing this argument and accepting its veracity, there is no reason to disbelieve the materials of which they are formed, to be the same. Schiaparelli supposes the nuclei of comets to consist of a solid substance, which being subject to a kind of "weathering process," finally becomes broken up into separate pieces, which are turned into a meteoric swarm by the attraction and atmospheric resistance of a large planet. To this effect he again quotes Schiaparelli. Further on he expresses it as his opinion that comets and meteorites are the remains of planets, the former being their fluid and the latter their solid constituents. It must be left to future observers to decide whether the apparent disappearance of Biela's comet has any connection with the rich fall of stars observed on November 27, last year.

It is possible that the vapour left in consequence of the gradual evaporation of a comet would condense, in the absence of any powerful centre of attraction, into a number of separate centres, as a cloud is dissolved into raindrops on the increase of cold. In this way the condensed portions of cometary vapour would present the phenomenon of numerous shooting stars as they penetrate the earth's atmosphere in a solid or perhaps still fluid condition.

PHYSICO-CHEMICAL RESEARCHES ON THE AQUATIC ARTICULATA *

IN NATURE, vol. iv. p. 245, we gave a brief notice of some investigations M. Plateau had been making on the above subject. Since that time he has been continuing his researches in the same direction, and sends us an abstract of the results so far as concerns three problems in the life of aquatic Articulata.

I. Experiments to ascertain the length of time that aquatic insects can remain under water without coming to the surface to breathe.

The swimming aquatic Articulata which breathe air come frequently to the surface to renew their supply. The questions, How long may they with impunity remain submerged? what is their power of resisting asphyxia, as compared with that of terrestrial insects? are answered by the following experiments. At the bottom of an open vessel, of one litre capacity, full of ordinary fresh water, is placed a very small vessel, containing about 200 cubic centimetres. A piece of cotton netting so covers the mouth of the latter, that an insect, placed in the small vessel, is in reality in the general mass of the water, but cannot ascend to the surface. Terrestrial insects placed in these conditions, impelled by their specific lightness, rise to the lower surface of the network; the movements of their legs soon cease, they do not appear to suffer, and they quickly grow torpid. The Coleoptera and aquatic Hemiptera, on the contrary, instead of submitting passively to their fate, endeavour to quit their prison, swim rapidly about, exert themselves to come to the surface, and keep struggling until their strength is enfeebled, and end by lying at the bottom as if dead.

In order to recover from its state of general torpidity an insect which has been submitted to prolonged immersion, it is necessary, after having taken it out of the water, to place it upon absorbing paper. If the time of its immersion has not passed a certain limit, the animal gradually recovers its energy, retaining no sensible trace of the experiment to which it has been submitted. M. Plateau repeated the experiment upon many individuals and for various lengths of time, for the purpose of discovering, in the case of each species, the limit of time beyond which immersion caused the death of the insect. He arrived at two curious conclusions, supported by a great number of trials :—

1. The terrestrial Coleoptera recovered from complete submersion continued for a very long time, in several cases for 96 hours. 2. The aquatic swimming Coleoptera and Hemiptera, far from presenting a greater resistance to asphyxia by submersion than the terrestrial insects, in most cases succumbed very much sooner.

The cause of this unexpected inferiority in the case of the aquatic insects M. Plateau thinks is due exclusively to their greater activity in the water, causing as a consequence a more rapid loss of oxygen.

II. Influence of Cold: Effects of Freezing.

The results of M. Plateau's experiments in this direction are that the aquatic Articulata of the latitudes of Belgium exist for an indefinite period in water maintained at zero (centigrade) by means of melting ice; while they cannot remain alive in ice for any length of time—not for half an hour at the utmost. The latter phenomenon appears to be accounted for by the fact that the insects are completely deprived of all power of motion, thereby losing completely their animal heat.

III. Action of Heat.

Under this head M. Plateau tries to show the maximum temperature of water in which fresh-water Arachnoids can live. He finds that the highest temperature they can endure without injury oscillates between 33°·5 and 46°·2 centigrade. Comparing these results with those which have been obtained by experimenting with animals belonging to other groups, M. Plateau finds that the greatest temperature which aquatic vertebrata, articulata, and molluscs can support probably does not exceed 46° centigrade.

* By M. Felix Plateau.

NOTES

WE have received a communication from Dr. Rein, Director of the Lenckenberg Society of Naturalists at Frankfort, which amusingly illustrates the perils that accompany the honours of the translation into a foreign language of a scientific work. Our informant relates that the well-known publisher, M. R. Oppenheim, of Berlin, having recently obtained the sanction of Mr. Poulett Scrope for the publication of a German translation of his work on "Volcanoes," of which a new issue lately appeared in this country, confided the work of translation to Prof. G. A. von Klöden, who accordingly performed the task. The translation was printed, together with a preface written by M. von Klöden himself—which preface, in the hurry of business, and in reliance, of course, on the good faith of the translator, the publisher forebore from examining. The volume in due course appeared, and was circulated by the publisher; and not till then was it discovered that the preface aforesaid consisted of a severe and indeed bitter critique of the work to which it was prefixed, and of the author's views as therein stated of the theory of volcanic energy, and its external development in the formation of cones and craters, &c. The explanation is that Prof. von Klöden happens—unluckily for the author whose work he undertook to translate—to have been all his life an earnest advocate and teacher of the famous "Erhebungs-Krater," or "upheaval crater" theory of Humboldt and Von Buch, which Mr. Scrope, together with Sir C. Lyell, Constant Prevost, and other geologists have persistently opposed, and are, we believe, generally considered to have satisfactorily refuted. Of course it is open to Prof. von. Klöden to expound and defend his own opinion on this subject to the fullest extent in any independent publication; but it does seem to be stretching the liberty of free expression on

scientific questions in an unprecedented manner, when a gentleman employed to translate a scientific work takes advantage of the opportunity to append to the translation, in the disguise of a preface, a pamphlet of nineteen pages containing an elaborate refutation, according to his own ideas, of the bulk of the views contained in the work itself. Mr. Scrope, we understand, on becoming aware of this strange conduct of Prof. von Klöden, has endeavoured to meet the attack thus unfairly made on his work, by circulating as widely as possible through the scientific world of Germany, a translation of his essay on the formation of volcanic cones and craters, originally read before the Geological Society of London in February 1859, and published in the journal of the Society for that year, a paper in which the theory of "Erhebungs-Kratere" was amply discussed. But even here the author appears to have had but scant justice done to him, if it be true, as Dr. Rein assures us, that "the German of this translation is *very bad!*"

AN Icelandic gentleman sends to the *Scotsman* an account of the eruption of the Skaptar Jokull in Iceland, which took place in January last. On January 9, about three o'clock A.M., there was observed from Reykjavik a great fire in the E.N.E. The fire shot up like lightning, displaying beautiful evolutions in combination with the electricity above. So bright was it, that during the dark morning hours it was thought it must be very close to Reykjavik. But when daylight dawned, and the mountains could be discerned, a thick and heavy column of vapour or steam was observed far in the background, beyond all the mountains, so that it was clear that it was far off, and, according to the direction, it seemed most likely to be in Skaptar Jokull, the west part of Vatna Jokull—the great waste of glaciers in the east and south of the island. Morning and night this grand display was visible during the 9th, 10th, 11th, and 12th, and during the day the column of steam and smoke stood high in the sky. All agreed that the eruption must be in Skaptar Jokull, and from various observations it was concluded that the position of the crater ought to be between 67° 7′ and 67° 18′ deg. north lat., and 30° 45′ and 30° 55′ west long. from the meridian of Copenhagen. In the east, near Berufjord, some shocks were felt, and fire was seen from many farms. Ashes, too, had fallen over the north-east coast so abundantly that pasture fields were covered, and the farmers had to take their sheep into the huts and feed them. In the south, however, no earthquakes were felt, or noises heard in the earth, as far as Markarfljol (near Eyjafjalla Jokull). Nowhere has been observed any fall of ashes or dust, but all aver a bad smell was felt, which was also the case in Reykjavik on the forenoon of the 10th. At Reykjavik the air was felt to be very close, with a smell of sulphur and powder. No change was observed in the sun, moon, &c. The sky was clear all these days. The direction of the wind was from N.W.—W.S.W., and the weather fine.

BARON LIEBIG is seriously ill, and on the 15th inst. there had been a great change for the worse in his condition.

ON Tuesday, Dr. James Murie, late Prosector to the Zoological Society, was unanimously elected by the Town Council of Edinburgh, Professor of Anatomy and Zootomy to the Veterinary College of that city, *vice* Professor Davidson, M.D., deceased.

PROF. ANSTED, whose unfortunate accident we noticed last week, has recently received from the King of the Greeks the brevet and insignia of the Hellenic order of the Sauveur, of which he has been nominated an officer, in recognition of his services in reference to the Laurium question.

M. LOEWY has been elected a member of the French Academy of Sciences in room of the late M. Delaunay.

A COMMITTEE was formed last autumn with a view to secure some provision for the five children who were left unprovided for by the untimely death of Mr. John Cargill Brough. A meeting of this Committee was held at the London Institution on Tuesday last, and the report of the Honorary Secretaries showed that the subscriptions amounted to a sum which, after deducting all expenses, will stand at nearly 2,000*l*. In this sum are included a grant of 150*l*. from the Royal Bounty Fund, 200*l*. contributed by members of the Savage Club, and nearly 400*l*. collected in answer to an appeal to the Pharmaceutical Chemists. A deed of trust of the usual character was approved by the Committee, and trustees were appointed. Votes of thanks were passed to Mr. McArthur, M.P., who has given a presentation to Christ's Hospital, to Mr. Deputy Webster, and to Sir John Lubbock, Bart., M.P., F.R.S., who has kindly acted as treasurer of the fund. The secretaries stated, in concluding their report, that the names of the gentlemen who have acted on the Committee, as well as the kindly expressions of sympathy which have from time to time reached them, afford evidence of the respect and affection in which Mr. Brough's memory is held.

AMONG the candidates for the Professorship of Anatomy to the Royal Academy are Dr. B. W. Richardson, F.R.S., and Mr. John Marshal, F.R.S.

DR. B. W. RICHARDSON, F.R.S., has been elected by the President and Council of the Royal Society, Croonian Lecturer on the subject of muscular motion.

THE third part of the great map of Switzerland ("Topographischer Atlas der Schweiz"), containing the sheets Binnenthal, Helsenhorn, Andermatt, Six Madun, S. Gotthard, Faido, Olivone, Hinterrhein, Mesocco, Jungfrau, Adelboden, and Lenk, has recently been issued at Berne. These sheets are all on the scale of $\frac{1}{50000}$. Those called Andermatt and S. Gotthard have a special and general interest at the present time from embracing the course of the Great St. Gotthard tunnel, and exhibit in the clearest manner, by means of their contour lines, the nature and altitudes of the overlying land. Thirty-eight sheets are now published out of the 546 which will compose this magnificent map.

MR. E. L. LAYARD, H.M. Consul at Para, well known for his zoological researches in different parts of the world, has returned to England, resigned his consulate in that place, and accepted the charge of the British interests in the Fiji Islands. During the short time he has held his office in South America, he has made a valuable collection of birds, of which we understand an account will be given in one of the forthcoming numbers of the *Ibis*.

THE new gate to the Zoological Society's Gardens in the Albert Road, opposite Primrose Hill, and the new canal bridge, opened on Easter Monday for the first time, were found very convenient to those of the 42,320 visitors on that day who arrived from the north, as they were saved the trouble of going over the rather out-of-the-way bridges of the Regent's Canal, which they previously had to do.

WE understand that Mr. Severzow, a well-known Russian naturalist of Moscow, is preparing a work on the zoology of the vertebrata of Turkestan, which will be accompanied with illustrations of the new and interesting species which have been the first-fruits of the new Russian Expedition and Annexations in that part of Asia.

THE Lucasian Professor of Mathematics (Mr. Stokes) at Cambridge, will deliver a course of lectures on hydrostatics, hydrodynamics, and optics, commencing Friday, April 25, and they will be continued, with a few exceptions, on all week days except Thursday, at the hour of 1 P.M., in the New Museum. Gentlemen who wish to attend are requested to leave their names with Messrs. Deighton. Mr. J. W. Clark will commence his osteo-

logical demonstrations in the Museum of Zoology and Comparative Anatomy, on May 12. The Demonstrator of Comparative Anatomy will resume his class for practical work on May 1, and continue the same on Thursday, Friday, and Saturday. Courses of lectures on History, Languages, and the various sciences, will be delivered at Cambridge to women during the Easter Term. The fee for each course is one guinea, but a reduction of one-half may be obtained on application by persons engaged in or preparing for the profession of education.

We hear that a Natural History Society and Field Club is about to be formed among the members of the Working Men's College, Great Ormond Street. The list of classes in the College for the term commencing April 21, announces a series of Saturday afternoon geological excursions, under the guidance of Mr. Logan Lobley, F.G.S. A course of lectures in Physiology is to be begun by Mr. S. D. Darbishire, M.A., Ball. Coll. Oxf. Mr. T. Hughes, M.P., who is now the Principal, will preside at the meeting with which the term opens on Monday evening next, and to which the public are admitted.

We have received from Prof. Cope several photographs of the cranium of the hugh horned Proboscidians of Wyoming, named by him *Loxolophodon cornutus*. This genus differs from *Dinoceras* of Marsh, which it very closely resembles in all respects, in having the nasal horn cores flat and horizontal, overhanging the apices of the nasal bones. The maxillary horn cores are also proportionately longer, and are not a continuation in direction of the enormous canine teeth, but are turned somewhat forward. Prof. Cope divides the short-footed Ungulates, or Proboscidians of the North American Eocene, into two families, the Eobasiliidæ and the Bathmodontidæ, the former possessing no incisors and no third trochanter to the femur, the latter having the full complement of incisors and a rudimental third femoral trochanter. He further divides up the Eobasiliidæ into the genera Loxolophodon, Eobasileus, Uintatherium, and Megaceratops, and the Bathmodontidæ into Bathmodon and Metalophodon. From a comparison of the photographs above mentioned with Prof. Marsh's drawing of *Dinoceras mirabilis*, we fail to see any points sufficient to justify their generic separation. On photograph shows clearly that in the molar teeth the outer wall was not present, and that the transverse ridges were fully developed, being straight but not parallel, meeting on the inner border of the tooth to form a >-shaped surface.

The Museum of Comparative Zoology, of Cambridge, U.S., in addition to the Bulletin of its proceedings, issues a series of "Illustrated Catalogues," in small folio form. In this several valuable papers have already appeared; but by far the finest and most important is one just out of press entitled "A Revision of the Echini," by Alexander Agassiz. This embraces an exhaustive account of the bibliography of the subject, as well as its synonymy, followed by detailed descriptions of the genera and species, both as regards the external form and internal anatomy. It is illustrated by forty-nine plates, of which seven represent the geographical distribution of the various groups of *Echini*, the remainder being devoted to representations of the species. A very important experiment has been made in this work as to the availability of different methods of photographic printing for natural history work, and, we may indeed say, with complete success. About one-third of the illustrations of species are crayon drawings on stone, one-third are Albert-types, prepared under the direction of Mr. E. Bierstadt, of New York, and the remainder are Woodbury-types, executed by Mr. John Carbutt, of Philadelphia. Nothing can exceed the perfection of finish and detail of the plates prepared by both these methods, and we are sure the work will mark an era in the history of scientific publications. The expense of even an approximation to the accuracy of these figures, on stone or metal, would have been enormous.

The Special Correspondent of the *Daily News* on board the *Challenger*, writing from St. Thomas on the 24th ult., states that the vessel was to proceed on her voyage that afternoon. All the scientific staff had been busy, and a large collection of interesting and beautiful objects had been made. On the previous Saturday morning the *Challenger* stood out to sea for the purpose of making magnetic observations, returning in the afternoon, and mooring in the inner harbour in readiness to sail the next day. Late in the evening, however, the *Challenger* acted the Good Samaritan to a dilapidated ship and her crew, lying fifteen miles off.

Professor Agassiz sends us part of the correspondence which took place between himself and Mr. Anderson, the gentleman who made the princely gift of a beautiful island and 50,000 dollars to Prof. Agassiz, referred to in the letter from a New York correspondent in last week's Nature. The whole affair has been gone about in the most simple and modest way by Mr. Anderson, who, in a letter to the Professor, hopes the school to be establisbed on Penikese Island "may be destined in future ages not only to afford the required instruction to the youth of our own country, but may be the means of attracting to our shores numerous candidates from the Old World, who may find here, in the school to be established by you, those means of fitting themselves for the teaching of Natural History by Nature herself, which, by a strange oversight, appear to have been overlooked in the schemes (generally so well conceived and executed) of education there."

The course of twenty-four lectures on Zoology, given during the past winter by Mr. J. E. Taylor, F.G.S., in the Museum, Ipswich, has been a great success. Every Friday night the great hall and galleries have been crowded, the audiences increasing as the lectures advanced, so that latterly upwards of 500 people have been in the habit of attending—a very satisfactory audience for a town of the size of Ipswich.

M. Faye has written to contradict a report in the *Revue Scientifique* that he had demitted his post of President of the Commission on the Transit of Venus, because he saw that the necessary instruments would not be ready in time. He was compelled to take this step on account of his many other public duties, and declares that he has no doubt whatever of the success of the French preparations.

M. Boillot, in making some experiments with ozone, has discovered that a litre of pure oxygen yields only 7 milligrammes of ozone, while the same quantity of air gives 37 milligrammes. Thus, *Les Mondes* says, oxygen mixed with air is in a condition more favourable to its being converted into ozone.

According to the *American Artisan*, measures are pending at Washington seeking to secure an international coinage of silver, for the immediate use of nations in America and Europe, now embracing a population of more than one hundred and sixty millions, and for the eventual use of all the civilised countries of the world.

Mr. W. F. Denning of Bristol sends us the following meteorological notes. A correspondent writes him that, on November 27, 1872, he was in latitude 43° 24′ north, and longitude 13° 55′ west, when at about $5^h\ 30^m$ to 6^h he witnessed a magnificent shower of meteors, which continued without intermission till nearly 8^h. Most of them were colourless, but some were tinted with a pale bluish hue. The seeming directions were from about N.E. by E., true, to S.W. by W., but the sky appeared so full that it was hard to tell. On April 6, at $9^h\ 8^m$, a meteor nearly as bright as Venus was observed by Mr. Denning at Bristol. Beginning of observed path = R.A. 83°, D. 43° +, end of ditto = R.A. 56°, D. 31° +, length of path = 24°. Duration 1·5 sec. Mr. Denning observed displays of aurora

borealis on the evenings of April 1 and 2. On April 1 it was first noticed at $8^h\ 49^m$, when an intense auroral glow pervaded the N. sky and gave an effect similar to moon-rise. At $8^h\ 51^m$ a broad streamer became visible, reaching a height of 11°. This streamer was situated 2° N. of β Cassiopeiæ, and appeared to be connected with an auroral arch under Cassiopeia, running from N.W. to N. On the following evening, April 2, the auroral light was again intense in due N.

THE additions to the Zoological Society's Gardens during the last week include a Bacha Eagle (*Spilornis bacha*) from Malacca, presented by Mr. W. Jamrach; a Madagascar Porphyrio (*Porphyrio Madagascariensis*) from Madagascar, presented by Miss Furlonger; a Cuttle-fish (*Octopus vulgaris*) presented by the Brighton Aquarium Co.; a great grey Shrike (*Lanius excubitor*) presented by Mr. Hawkins; a Crested Pelican (*Pelecanus crispus*) from S. Europe, presented by Dr. Doyle; a Vulpine Phalanger (*Phalangista vulpina*); a great Kangaroo (*Macropus giganteus*); a yellow-footed rock kangaroo (*Petrogale xanthopus*); and some Tibetan Wolves (*Canis laniger*) born in the Gardens; two Hunting Crows (*Cissa venatoria*) from India; a Cocoi Heron (*Ardea cocoi*) from the W. Indies; a Broad-banded Armadillo (*Xenurus unicinctus*) from Brazil; two Rock Whiting; a Whiting Pout, two Lump-fish, and six Bream all purchased.

ON AN AIR-BATTERY*

THIS battery is founded on a reaction, brought by the authors before the Royal Society† last spring, in which it was shown that if pieces of copper and silver, in contact, were immersed in copper nitrate solution in presence of oxygen, a deposit of cuprous oxide took place on the silver plate with a corresponding solution of the copper plate, resulting from the decomposition of the copper nitrate in the manner shown in the following formulæ:—

Before contact is made

$$mAg \mid O \mid Cu2NO_3 \mid Cu2NO_3 \mid nCu$$

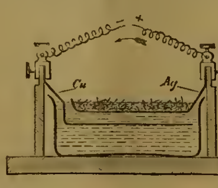
After contact

$$mAg \mid Cu_2O \mid Cu2NO_3 \mid Cu2NO_3 \mid (n-2)Cu$$

It is evident that this action is continuous until either the copper or the oxygen is exhausted.

It was stated in that paper, that a galvanic current passed through the solution from the copper to the silver, and also that this was only one case of a large class of similar reactions.

The battery takes the form of a shallow circular vessel containing the solution, and the plates are arranged horizontally, the silver plate being at the surface. It will be apparent on glancing at the above equations, that the combination of the oxygen only



takes place in the neighbourhood of the silver; hence it was evidently desirable to increase as much as possible the proximity of the silver plate to the air, and also the surface exposed by the silver. This was accomplished as shown in the adjoining sketch. The silver has the form of a shallow tray, full of crystals of silver, and perforated to allow the circulation of the copper solution. The tray is arranged so that the crystals should just rise above the surface, and being, of course, always wet, they very much increase the absorbing surface of the liquid. The whole arrangement is put upon a wooden stand, and the plates are attached to two uprights fixed in the stand.

The strength of the copper nitrate solution is 6 per cent. This gives about the maximum of effect; a 24 per cent solution gives only half the current; and a 30 per cent solution gives two-thirds. A solution stronger than 6 per cent. is also apt to produce a deposit of subnitrate instead of suboxide.

The best proportionate areas of the silver and copper-plates was investigated in two series of experiments, in one of which the silver remained the same, while the copper surface was diminished by varnishing, and in the other set the copper remained the same while the silver was diminished. The following table gives the results in the latter case. The deflections are those of a Thomson's galvanometer:—

Proportion of Surfaces.		Deflection.		
Copper	Silver.	Expt. 1.	Expt. 2.	Expt. 3.
1	0·25	—	—	7°·5
1	0·5	—	—	16°·0
1	0·75	—	—	21°·0
1	1·0	33°	32°	28°·0
1	1·33	41°	40°	—
1	2·0	56°	54°	—
1	4·0	96°	92°	—

It thus appears that an increase in area of the silver plates causes a proportionate increase in the current. It was also found that heat greatly increases the activity of this cell, a cell giving a deflection of 40 at 20° C., gave one of 250 at 50° C.; and the increase in the higher degrees of this range of temperature was much greater than in the lower.

From the nature of the reaction it might be expected that the current would gradually diminish on account of the using up of the oxygen in the neighbourhood of the silver. Such a diminution always does take place at first—agitating the liquid ought, under these circumstances, to increase the action. It does so.

It might also be expected that upon breaking contact for some time, so as to allow oxygen to diffuse itself from other parts of the solution, the current upon again making contact would be as strong, or nearly so, as before. This also was found to be the case.

An experiment was made by putting a cell, with plates connected by a wire, under a bell-jar full of air over mercury. It was expected that the mercury would rise inside the jar from absorption of the oxygen. The mercury did rise, and the oxygen was so completely removed that a lighted taper was immediately extinguished in the remaining gas. The apparatus used in this experiment was exhibited to the Royal Society.

Comparative experiments were made with aërated and de-aërated copper nitrate solution. It was found that the amount of action in the latter case was little or nothing, and what small action there was was clearly attributable to the difficulty of completely excluding air.

Two experiments were made alike in all respects, except that in one case the cell used was filled with a solution simply deprived of oxygen, while the other cell was filled with a solution through which a current of CO_2 was passed for some time. The first was placed in the air, and gave a deflection of 110 rising to 115, but the second was placed in a vessel full of carbonic acid gas, and gave a deflection of 20, which gradually fell to 3.

It was proved experimentally that the cuprous oxide deposited on the silver was compensated by an equivalent solution of the copper plate. The cuprous oxide is sometimes deposited in crystals visible to the naked eye, and shown by a lens to be regular octahedra.

One cell having plates two inches in diameter was found sufficient to decompose such metallic salts as the nitrates of copper, silver, and lead, platinum being used for the negative electrode, and for the positive the same metal as existed in the salt experimented on. Six cells were sufficient to decompose dilute sulphuric acid and dilute hydrochloric acid pretty quickly, copper electrodes being employed.

The theoretical interest of this battery lies in the fact that it differs from all other galvanic arrangements, inasmuch as the binary compound in solution is incapable of being decomposed

* Abstract of paper read at the Royal Society, Thursday, April 3, by J. H. Gladstone, Ph.D., F.R.S., and Alfred Tribe, F.R.S.

† Proc. Roy. Soc. vol. 20, p. 290.

either by the positive metal alone or by the two metals in conjunction, without the presence of another body ready to combine with one of its elements when let free.

Grove's gas battery is essentially different from this, if the oxygen and hydrogen condensed on the platinum plates play the part of the two metals; but it closely resembles this if hydrogen acts the part of the positive metal, and platinum that of the negative; the dilute sulphuric acid will then be decomposed on account of the simultaneous presence of the oxygen which can combine with the liberated hydrogen. Viewed in this manner, Grove's gas-battery is only a special case of the reaction mentioned in the communication to the Royal Society, and the formulæ will be—

Before contact—

$$m\,Pt \mid O. \mid H_2SO_4 \mid n\,H$$

After contact—

$$m\,Pt \mid H_2O \mid H_2SO_4 \mid (n-2)\,H.$$

The practical interest of this arrangement lies in the fact that it is an approximation towards a constant air-battery. Should it ever come into use it would, of course, not be in the form described in this paper, but probably in a combination of copper and zinc, with an aërated solution of zinc chloride, which has an electro-motive force six times that of the silver-copper cell, and three quarters that of a Daniell's cell. Chloride of zinc is preferable to the sulphate, as it offers less internal resistance, and a solution of 20 per cent. is about the best conductor. A single cell of this kind decomposes dilute sulphuric or hydrochloric acid, with copper electrodes.

The power is thus obtained at a minimum of expense, for the oxygen which combines with the zinc costs nothing.

Such a battery would appear to be specially applicable to cases where the galvanic current has to be frequently broken, as in telegraphy, for, at each period of rest, it renews its strength by the absorption or diffusion of more oxygen from the surrounding air.

SCIENTIFIC SERIALS

Zeitschrift für Ethnologie.—The second number of this journal for 1872 scarcely possesses the same scientific value as former numbers. We have, first, the concluding part of Dr. E. von Martens' lecture, read before the Anthropological Society of Berlin, December 1871, on the different uses of the Conchylia. The paper is characterised by true Germanic exhaustiveness, but it indicates a want of appreciation on the part of the author of the relative value of authorities, ambiguous allusions in Longfellow's "Hiawatha" being adduced as evidence, side by side with the statements of scientific travellers. Dr. Martens passes in review every use to which shells have been put in ancient or modern times, and in civilised or uncivilised countries.—Dr. Robert Hartmann continues his notice of the remains found in the Lake Dwellings of Switzerland, and draws attention to the absence of the domestic cat from the more ancient fauna of Europe. The most numerous animal remains belong to the common European stag (*Cervus elephas*), but are of colossal size, and so nearly akin to *Cervus Canadensis* as to raise the question whether the *C. elephas* of the Swiss Lake deposits may not be identical with *C. canadensis*. No trace of reindeer has been discovered, although that animal was common in Switzerland during the glacial period.

In the third number (1872) of the journal, we have an interesting report of the remains of pile dwellings in the Archipelago of North Celebes, which have been examined by the Dutch "Assistant Resident," J. G. F. Riedel. The paper is illustrated with drawings of these huts, and of the different types of head most commonly observed among the North Celebes tribes in the present day. It would appear that the Aborigines were not lake-dwellers. The Toun Singals, however, who were of foreign origin, and arrived in the country between the 12th and 13th centuries, although they at first dwelt on the strand of the present Negeri Atep, soon left their original settlements, and built themselves pile-huts on the great Minahasa Lake, where they were secure from the pursuit of the robber tribes of Djailolo, whose incessant attacks had been the chief incentive to their immigration. The remains of these lake-dwellings give evidence of their solidity, for Herr Riedal found that the piles were for the most part 3 ft. in diameter, and 20 ft. in height above the surface of the lake; the length of each hut was nearly 70 ft., and the breadth 40 ft. Among other events the enforced conversion to Christianity of the Toun Singals in 1830 has separated them still more from the habits of their race, and the memory of the older pile-dwellings seems to be fast dying out among them.

Dr. Bastian gives us in the third number a very complete and carefully elaborated paper on Comparative Philology. He begins by treating of the physiological formation of speech; and of the widely differing groups of emotions which respectively find expression in vocals and in consonants. He passes in review the various nations, whose original language exhibits a preponderance of either of these distinctive characters. Among the older races of America and Africa consonants largely predominate, while in the Malay Polynesian dialects vocal sounds are strongly in the ascendent. The phonetic character of a language influences its grammatic peculiarities.

Herr Rade, who has spent eight years in endeavouring to discover among the Kaukasian tribes some fixed type of their nation, finds from his prolonged investigation of living and dead skulls that the mingling of races has been so continuous in these regions, that it is impossible any longer to recognise the "Kaukasian Race" as it was defined by Blumenbach. Herr Rade has hitherto failed in detecting certain evidence of the existence of Lacustrine dwellings in any of the Kaukasian lakes which he examined.

Dr. Virchow, at a recent special meeting of the Anthropological Society of Berlin, read an interesting paper on the results of a series of explorations made by himself and his sons in the course of last year in the little island of Wollin, lying off Pomerania, in the Baltic. Wollin or Julin as the locality in which the sea-kings or Vikingar had established their once formidable republican settlement of Jomsburg, has always presented special features of interest for Northern inquirers and historians. The early chroniclers of Northern Germany and Scandinavia make frequent allusion to the enormous wealth and great importance of the trading ports of this small island. After ages of decay and desertion the island is again acquiring some slight amount of recognition through the recent establishment of baths near the little town of Wollin. It is here that Dr. Virchow and his sons found unmistakeable evidences of the early existence of a large and wide-spread population. Near the little lake of Vietzig, under a surface of loam or clay-mud, Dr. Virchow came upon a bed of *débris* from 4 to 7 ft in depth, which was entirely formed of fish and animal bones, broken vessels, and all the ordinary adjuncts of the Kjokkenmöddinge as they have been revealed in the Lacustrine deposits of Pomerania. At some places where the hills have been cut, the exposed surfaces seem composed almost entirely of the scales and bones of fishes and other animal remains. At one spot, on the S.E. of the present town, a burying ground was discovered, on which 60 grave-hillocks could still be counted. On penetrating below the surface a heap of burnt and fractured bones was found at a depth of 18 to 20 in., but in no grave, explored by Dr. Virchow, was any trace of urn, stones, or textile fragment to be seen; although remains of fused bronze were met with. A small grant of money has been made by the Society for the purpose of continuing the exploration of the island, and if the work should be placed under the direction of Dr. Virchow we may anticipate valuable results from a more systematic investigation of this site of the most formidable piratical republic ever founded in Northern Europe.

In a paper laid before the Societé d'Anthropologie de Paris by M. Broca, on the Toulouse form of narrow or flat-head deformities, the author enters at length into the consideration of the probable effect on the cerebral functions produced by the ligatures, with which the peasant mothers of some parts of south-west France still compress their children's heads.

THE *Zoologist* for April, after a reprint from the *American Naturalist* of Prof. N. S. Shaler's paper, "Notes on the Right and Sperm Whales;" and ornithological notes from Lincolnshire and Devon, enters further into the discussion of Dr. Baldamus' theory as regards the cuckoos' egg. Mr. Hewitson replies sharply to Mr. Smith's paper in the preceding number; Mr. G. D. Rowley opposes the theory, and thinks that "birds are only too glad to sit on cuckoos' eggs," as they will sit on nothing rather than not incubate. Mr. Doubleday writes to the same effect, as does also Prof. Newton in a quotation from the *Field*. Mr. Smith acknowledges that in writing his former letter, he had not seen Prof. Newton's article on the subject in NATURE (vol. iii. Nov. 1869), but still maintains that British

ornithologists have not yet investigated the question "in the systematic way, and after the excellent example of painstaking and diligence set us by Dr. Baldamus and Dr. Rey." The editor, referring to a note on the Liberian Hippopotamus which appeared in this periodical a month ago, states that the author has made a mistake in calling it a true hippopotamus. The context clearly shows how the term is meant, and it is an undoubted fact that the English name has a wider meaning than its Latin equivalent. Chœropsis is as true a hippopotamus as Rhinaster or Ceratorhinus are true rhinoceroses, and they are so undoubtedly in the English acceptation of the words, so we think Mr. Newman too ready in discovering errors.

THE *Canadian Naturalist and Quarterly Journal of Science*, vol. vii. No. 1.—The first paper in this number is one which we have already received in a separate form, viz. Principal Dawson's Address as President of the Natural History Society of Montreal. He discusses, (1) The present aspect of inquiries as to the introduction of genera and species in geological time. (2) The growth of our knowledge of the Primordial and Laurentian rocks and their fossils. (3) The questions relating to the so-called glacial period. This is followed by a paper on Some Results of the last Solar Eclipse, in which the author, Mr. G. F. Armstrong, sums up briefly the results which have been obtained from the eclipses of 1865 and succeeding years. In a paper on Cuba Mr. G. F. Matthew makes some contributions to our knowledge of the natural history of that island. There is a geological paper on Huron County, Ontario, and another on the Mineral Region of Lake Ontario. The last paper in the journal is the obituary notice of the late Prof. Sedgwick, which appeared in NATURE.

SOCIETIES AND ACADEMIES

LONDON

Geologists' Association, April 4.—Professor Morris, F.G.S., vice-president, in the chair.—"On the Diamond Fields of South Africa," by Mr. G. C. Cooper.—The theory of an igneous action upon the spot at which the diamonds are now found being the explanation required to solve the problem of their origin was opposed by the author, who adduced facts from his observation in support of the opposite conclusion. He did not consider that the numerous trap dykes which characterise the South African Diamond Fields broke through the present surface, which, on the contrary, had been produced by the accumulation of materials brought by aqueous agency subsequent to the volcanic action which gave rise to the dykes. These materials consisted of a surface layer of red sand overlying a bed, from five to seven feet thick, of fragments of "lime and clay stone;" and beneath this the diamantiferous marl or "stuff" is reached. Steatitic or magnesian matter forms a considerable proportion of the "stuff" which it was contended may have been brought from magnesian rocks at a considerable distance by water and possibly by ice action, and deposited in the hollows formed by the trap dykes, and that these magnesium rocks may have been the original matrix of the diamonds.—"On some Fossils from the Chalk of Margate," by J. W. Wetherell. The author had devoted some time and attention to the exploration of the chalk in the immediate neighbourhood of Margate, and had obtained, as a result, a large number of species of fossils, a list of which was given, with remarks as to relative abundance. In addition to many genera usually abundant in the Upper Chalk, *Belemnitella* appears to be well represented in the Margate chalk, and ammonites are also found; but perhaps the most abundant fossil is the *Coscinopora globularis*, which varies in size from that of a walnut to a pin's head. Crystals of selenite were found as well as concretions of iron pyrites, but minerals are by no means common in the chalk of Margate.

Mathematical Society, April 10.—Dr. Hirst, F.R.S., president, in the chair.—Prof. Clifford made a few remarks in correction of a statement he had made at the March meeting during the discussion on Mr. Hayward's paper on an extension of the term *area*.—Mr. J. W. L. Glaisher then proceeded to read a paper on the calculation of the value of the theoretical unit angle to a great number of decimal places.—The following papers (in the absence of the authors) were discussed by Messrs. Clifford, Cotterill, Merrifield, and the president:—On systems of porismatic equations, algebraical and trigonometrical; Note on epicycloids and hypocycloids; Locus of point of concourse of perpendicular tangents to a cardioid; Elliptic motion under acceleration constant in direction; Prof. Wolstenholme, on the theory of a system of electrified conductors; On the focal lines of a refracted pencil, Prof. J. Clerk-Maxwell.

Royal Horticultural Society, March 26.—Special general meeting, Lord Alfred Churchill in the chair.—The business practically consisted in the consideration of two bye-laws proposed by the Council. The first, giving to all the fellows the right of vote by proxy (hitherto restricted to ladies), was rejected. The second, impowering the fellows to elect to vacancies on the Council at a general meeting other than the annual general meeting, if more than half their number resign at any one time, was carried. Great excitement and disorder was manifested throughout the prolonged discussions.

April 2.—General Meeting, Mr. W. Saunders, F.R.S., in the chair.—A communication was read from Mr. Cocks, on budding vines. It was shown (1) that the extirpation of all the buds of the budded plant gave the inserted buds a better chance of success by removing competition, and (2) that there was no advantage in inserting new buds in the seats of those removed.

Scientific Committee, Dr. J. D. Hooker, C.B., F.R.S., in the chair.—Mr. Smee exhibited lemons infested with *Coccus limonii*, which caused the green colour of the unripe fruit to persist round the points of attachment, and injured the lemons for preserving purposes.—The Rev. M. J. Berkeley stated that the new potato disease described by Hallier in his "Parasitenkunde," was no doubt identical with the "copper-web" of the asparagus-growers of the Isle of Ely. It had been described as *Rhizoctonia*.—Dr. Hooker read a portion of a letter from Mr. Woodrow, stating that a succulent composite, *Notonia grandiflora*, had a great reputation as a cure for hydrophobia in the neighbourhood of Bombay.—Prof. Thiselton Dyer pointed out that the seeds of the Sooly Qua were not identical with those of *Luffa acutangula*; they much more resembled those of *Luffa ægyptiaca*.

April 6.—Special general meeting, Lord Alfred Churchill in the chair.—The following new members of Council were elected on the proposition of Lord Strathmore.—Viscount Bury, M.P., Hon. R. Chetwynd, Mr. Hardcastle, M.P., Sir C. Lindsay, Mr. W. A. Lindsay (Secretary), Sir A. Slade, Mr. Hellock, Mr. A. Smee, Mr. H. Little, Mr. R. Warner.

Institution of Civil Engineers, April 8.—Mr. T. Hawksley, president, in the chair. The paper read was "On the Rise and Progress of Steam Locomotion on Common Roads," by Mr. John Head, Assoc. Inst. C.E., and was divided into four parts:—1. Road locomotives for conveyance of passengers, also locomotives for use on tramways. 2. Road locomotives for conveyance of goods, heavy weights, &c., also steam road rollers. 3. Locomotives for use in agricultural operations, steam ploughing, &c. 4. Locomotives for military purposes.

Cambridge Philosophical Society, March 3.—Notes on the Hippopotamus, by Mr. J. W. Clark. The author exhibited the mounted skeleton, and some portions of the visceral anatomy, of the female hippopotamus which died in the London Zoological Gardens in January 1872, and made some remarks on the specimens.—"On the Foraminifera and Sponges of the Cambridge Upper Greensand," by Mr. W. J. Sollas. The author described the green grains abundant in the formation, and showed that, like those in many other rocks, they were to a large extent the casts of foraminifera. He then discussed the formation of the so-called coprolites, and showed that in a great number of instances these nodules were phosphatised sponges, just as the flints of the chalk were silicified sponges. He thought that the phosphate of lime might have been derived from the erosion of volcanic rocks in the south of Scotland which had been brought by a current from the north.—"On a Boulder in a coal seam, South Staffordshire," by Mr. Bonney. This boulder, found in the black coal of the Cannock and Rugeley Colliery, a seam nearly 3 yards thick, weighed 13 lbs. 13½ oz., was about 19 in. in girth either way, and about 4½ in. thick, it was of a compact grey quartzite, apparently identical with one of the rarities in the Bunter conglomerates of the district. He considered that the boulder, which was quite solitary, had been brought to its present position (probably during a flood) entangled in the roots of a tree—and discussed the bearings of its occurrence upon the physical geography of England in the carboniferous and triassic times.

MANCHESTER

Literary and Philosophical Society, April 1.—R. Angus Smith, Ph.D., F.R.S., vice-president, in the chair. "Note on an Observation of a small black spot on the sun's disc," by Joseph Sidebotham, F.R.A.S. On Monday, March 12, 1849, our late member Mr. G. C. Lowe and I saw a small circular black spot cross a portion of the sun's disc. We were trying the mounting and adjustments of a 7 in. reflector we had been making, and used an ink box between the eye-piece and the plane speculum. At first we thought this small black spot was upon the eye-piece, but soon found it was on the sun's disc, and we watched its progress across the disc for nearly half-an-hour. The only note in my diary is the fact of the spot being seen—no time is mentioned, but if I remember rightly, it was about four o'clock in the afternoon.—Mr. Baxendell said in a letter which Mr. Sidebotham had received from Prof. Hamilton L. Smith, of Hobart College, Geneva, New York, the writer suggests the use of iron or bell metal specula, coated with nickel, for reflecting telescopes. He says, "I ground and prepared a bell metal speculum, which I coated with nickel, and this, when polished, proved to be more reflective (at least I thought so) than speculum metal. The two objects which I sought were—first to have a polished surface unattackable by sulphuretted hydrogen (this, for example, is not injured by packing with lucifer matches), and secondly, for large specula, doing most of the work by the turning-tool and lathe. I really think a large, say 3 ft. mirror, coated with nickel, but cast of iron, and finished mostly in the lathe, while it would not cost the tenth of a similar sized speculum metal, would be almost equal to silvered glass of the same size, and vastly more enduring as to polish.—Prof. Williamson, F.R.S., referring to Mr. Binney's remarks at the meeting of March 4, said:—Mr. Binney, after pointing out that I had identified a certain type of stem-structure with *Asterophyllites*, and that Prof. Renault had discovered the same structure in *Sphenophyllum*, Mr. Binney proceeds to say, "I am not in possession of the facts from which the two learned professors came to *such different conclusions*, but I am inclined to consider the singular little stem as belonging to a new genus *until the leaves of Sphenophyllum or Asterophyllites are found attached to it*. When this comes to pass of course there can be no doubt of the matter." I have italicised the two important points in the preceding quotation. In the first place I cannot understand how Mr. Binney has overlooked my statement, made primarily in the Proceedings of the Royal Society, and repeated in the last number of the Proceedings of your meeting of February 4, that I *had* got a number of exquisite examples, showing not only the nodes *but verticils of the linear leaves so characteristic of the plant*." These leaves I have obtained attached to the stems in question in at least a dozen examples. Secondly, Mr. Binney considers that my conclusions and those of my friend Prof. Renault are *different*, whereas they mutually sustain each other in the strongest possible manner. E. W. Binney, F.R.S., said that after having heard Prof. Williamson's remarks his opinion expressed at the meeting of the Society on March 4 last was not altered.

GLASGOW

Geological Society, March 27.—Mr. James Thompson, F.G.S., vice-president, in the chair.—Mr. David Robertson, F.G.S., read some further notes on the post-tertiary fossiliferous beds of the West of Scotland. He first alluded to the brick-clays at Jordanhill, about a mile to the north-west of Partrick, and 145 ft. above the present sea-level. The clay here is wrought to a depth of from 12 to 20 ft., in some places rather more. One point of interest in examining the clays of this locality is the position in which the shells of the common mussel (*Mytilus edulis*) are found. This mollusc is commonly thought to have its zone or position near the surface, and to lie above the post-pliocene Arctic shells in the clays of the Clyde district. This no doubt is frequently the case, but it also occurs at greater depths, and overlaid by Arctic shells. Here it is found at a depth of 14 ft., while at a little distance in the same field Arctic shells occur within 6 ft. of the surface. Another feature of interest in the clays of this neighbourhood is the presence of portions of oak trees, some of considerable magnitude. Such pieces of oak, it is well known, are abundant in the peat of every district, but he was not aware of their having been previously found associated with Arctic shells in the clays of any part of the country.—Mr. Robertson then described the cuttings of the Maryhill Gasworks and Stobcross Railway, giving particulars of the beds exposed, especially in the latter, where interesting sections of boulder clay, gravel, sand, and laminated clay have been laid open during the excavations now in progress. The animal remains are sufficient to show the truly marine character of the deposit.—Mr. John Young read a paper on the probable derivation of certain boulders found in the till near Glasgow. He said the great majority of the boulders in the till of the Glasgow district had evidently been derived from tracts that lay to the west and north-west of the city. At the same time it was interesting to note that the ice which had travelled over the district had not proceeded exclusively from western or north-western sources, as the glaciated surface lately discovered at Possil clearly proved. There the rock is striated both from a north-west and a north-east direction; and he showed that the mineral constituents of the till quite corresponded with and confirmed these variations observable in the striæ.

MONTREAL

Natural History Society, Jan. 27.—During the past summer Mr. J. Richardson, of the Geological Survey of Canada, has made unusually large collections of the fossils, minerals, and other objects of interest from Vancouver and Queen Charlotte. Mr. A. R. C. Selwyn said that these collections establish conclusively the fact that the coal fields of the two islands belong to the same geological horizon. In each case the coal fields are of the same age as the chalk formation of Europe and elsewhere. Further, the coal of Queen Charlotte Island is found to be a true anthracite, and it is the first instance on record of the occurrence of anthracite in formations as new as the chalk. The coal seams of Vancouver rest directly upon crystalline rocks, in which limestones predominate. Mr. Richardson estimates the Comox coal field, in Vancouver, to have an area of 300 square miles. It is underlaid by coal seams of from 2 to 10 ft. in thickness, which would probably yield an average of 11,840,000 tons per square mile. The total production of this field, to a depth of 1,500 ft. from the surface, is computed to be about 3,552 millions of tons. The Nanaimo coal field has an estimated area of 90 square miles, and contains three or more seams of from 3 to 10 ft. in thickness. Specimens of carvings in wood and stone made by Queen Charlotte Islanders were exhibited. These evince considerable constructive ability, and are almost invariably of a grotesque character.—Mr. Billings gave a description of the distribution of the cretaceous rocks of North America, He then called attention to some of the characteristic fossils of the Vancouver and Queen Charlotte strata, and showed a series of some of the most striking specimens. Among these were large ammonites, nautili, and various marine shells, of the same genera for the most part as those which are frequent in the European chalk formation. He remarked that in the present collection he had not detected any remains of large reptiles, or any sea urchins, both of which are common in the cretaceous rocks of other localities.

PHILADELPHIA

American Philosophical Society, September 20, 1872.—The following papers were read by Prof. E. D. Cope—Third account of Vertebrata from the Bridger Eocene; notices of new extinct Vertebrata from the upper waters of Bitter Creek, Wyoming; from the upper waters of Bitter Creek, Wyoming; "On the existence of *Dinosauria* in the transition beds of Wyoming Territory." In the last it was shown that the coal series of Bitter Creek belonged to the cretaceous formation.—Prof. Houston described a sensitive waterfall in Pike Co., Pennsylvania.—Prof. Chase communicated observations on some new planetary and stellar distances.

October 18.—Two papers from Prof. Cope were read, viz.: "On a new Genus of Vertebrata from the Upper Green River Basin," and descriptions of new extinct reptiles from the same. The former embraced the description of a new genus of *Lemnidæ* or allied group, having the dental formula 2—1—2—3.

November 1.—Prof. Lesley presented a record of authentic data respecting fourteen oil wells in West Pennsylvania.—Prof. Chase presented a paper, "A first approximation to a normal curve of temperature in the northern regions of the continent."—Aubury H. Smith described his observations on the sub-alpine botany of the north shore of Lake Superior, and of its absence in the Lake Nibbegong region farther north, which he had explored in 1872, which he believed was due to the greater coldness of the waters of Lake Superior.—Dr. Leconte gave a hygrometric explanation for the phenomenon, believing similar ones known

to him to depend on the difference between dry continental air, and damp winds from sea coasts.

November 15.—Mr. Gabb described the results attained in tabulating Miocene fossils from Santo Domingo. He described 217 extinct and 19 living species, the latter found on both sides of the barrier of Central America, which is capped by Miocene rocks.

December 20.—Prof. Cope read a paper on the zoological regions of the earth, and especially those of North America, agreeing as to the first with Drs. Sclater and Wallace in the main, adopting the Australian, Neotropical, Ethiopian, Neoarctic, and Palæartic (including Palætropical of S. and W.), stating that all the southern continents present marked distinguishing characters. In North America he adopted the Pacific, Lower Californian, Sonoran, Central, Eastern, and Austroriparian, which in the main agreed with those of Baird, the last being the southern part of his eastern, as far north as the isothermal of 77½ F. The subdivisions were the Floridan, Louisianian, and Texan; those of the eastern after Allen, Carolinian, Alleghanian, Canadian, and Hudsonian.—Prof. O. C. Marsh gave an account of his discoveries in the Rocky Mountains since 1870, which included the first American *Chiroptera*, *Marsupials*, low forms of *Quadrumana*, birds with biconcave vertebræ, and several species of a new order, *Dinocerata* allied to the *Proboscidia*, but with horns and canine teeth.

January 3.—Prof. P. Fraser read a paper on a hydraulic problem, near Bethlehem Penna.

CALIFORNIA

Academy of Sciences, Dec. 18, 1872. "On the Parasites of the Cetaceans of the N.W. coast of America, with Descriptions of new Forms," by W. H. Dall, U. S. Coast Survey. Among the parasites most widely known as infecting the Cetacea, two classes may be recognised, viz., those which are true parasites, deriving their subsistence from the animal upon which they are found, such as the Pycnogonoids and Cyami, and those which are merely sessile upon the animal, and derive no nourishment or other benefit from it which might not equally well be furnished by an inanimate object, such as the various cirripedes.

VIENNA

I. R. Geological Institute, Jan. 21.—"Fossil Remains of Sirenoidæ found in the Venetian Territory," by Ach. Barone de Zigno. Besides the ribs and other bones of Halitherium which had been discovered many years ago in the upper tertiary beds of the Venetian Alps, the author succeeded in gathering a very rich collection of different species of Sirenoidæ in the lower tertiary beds (with Serpula spirulæa) of the Monte Zuello, near Montecchio, and in the glauconitic limestone of the basin of Belluno. The glauconitic strata of this basin had been taken till now for Eocene; but fossils found therein by Jaramelli—as *Clypeaster placenta* Des., *Scutella*, *Subrotunda* Lam, &c.—prove that they are of Miocene age.—"On the Eruptive Rocks of Styria," by R. von Drasche. The author gives an accurate petrographical analysis of the different eruptive rocks of Southern Styria, which by former observers had been taken for older porphyries, but which M. Stur has proved to be of tertiary age. They are andesites and trachytes. Some of these rocks resemble indeed very much older porphyries, and prove again the difficulty of discerning by mere petrographical or chemical properties eruptive rocks of different geological age.—A. Redlenbacher presented a memoir on the Cephalopods of the Gosau-strata of the Alps. Since the last publications on this matter by Fr. von Hauer, the number of species in our collections has more than doubled. Only eight of them are identical with species out of non-Alpine cretaceous strata, and they belong all to Senonian beds.

Feb. 18.—M. Tschermak gave an accurate description of the slates, quartzites, and limestones, along a section through the so-called Graywacke Zone of the North-eastern Alps, in the vicinity of Reichenau and the Semmering mountain. These rocks had been thought to belong to the Silurian formation, but in the opinion of M. Tschermak part of them were of a still older age. The study of the oldest sedimentary slates and other rocks of the Alps, promises, he thinks, valuable information about the genesis of the crystalline slates.—M. Fr. Foetterle "On the copper and iron ores of Ferriere in the province of Piacenza, in Italy." The valley of the Nure, extending from Piacenza in a south-west direction into the central part of the Appenines, in the upper part of its course is bounded by high mountain ranges, which consist of grey sandstones, alternating with bituminous slates and marls. They belong to the so-called macigno (Vienna and Carpathian sandstone) and are probably of Eocene age. In the highest parts of the valley, in the environs of Boli and Ferriere, the macigno is traversed by numerous masses and dykes of an eruptive rock which is partly gabbro, consisting of large crystals of amphibol and feldspar, and partly serpentine. These eruptive rocks are of a more recent age than the macigno, which is very much altered by contact with them. Partly in the eruptive rocks and partly in the adjacent altered macigno are to be found masses of copper- and iron-pyrites, and of magnetic iron ores; they form boulders of some size, but nowhere regular layers or veins. The mines which have been opened to gain these ores, M. Foetterle thinks, promise no great success.—O. Feistmantel on the relations between the carboniferous and the Permian formations in Bohemia. In some of the Bohemian coal-basins, *e.g.* that of Radowenz at the foot of the Riesengebirge, in the north-western environs of Prague, in the basin of Pilsen, &c., two layers of coal are known, both accompanied by vegetable remains of a pure carboniferous type; but the strata between these layers contain remains of fishes, as Xenacanthus, Acanthodes, Palæoniscus, &c., which belong to the Permian fauna. The author concludes that the upper coal layers of the Bohemian coal-basins belong to the Permian formation, and the lower only to the carboniferous formation, and that both formations are most intimately allied by their identical flora.

DIARY

THURSDAY, April 17.

LINNEAN SOCIETY, at 8.—Burmese *Orchideæ*, from the Rev. C. P. Parish: Prof Reicheobach.—Perigynium of *Carex*: Prof. McNab.

CHEMICAL SOCIETY, at 8.—On Heat produced by Chemical Action: Dr. Debus, F.R.S

NUMISMATIC SOCIETY, at 7.

ZOOLOGICAL SOCIETY, at 4.

SUNDAY, April 20.

SUNDAY LECTURE SOCIETY, at 4—The Theory of Wind Instruments: Dr. W. H. Stone.

MONDAY, April 21.

LONDON INSTITUTION, at 4.—Elementary Botany: Prof. Bentley.

GEOLOGISTS' ASSOCIATION, at 8—Visit to Museum of Practical Geology.

TUESDAY, April 22.

ROYAL INSTITUTION, at 3—Music of the Drama: Mr. Dannreuther.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion on Mr. Head's paper on Steam Locomotion on Common Roads—On the Delta of the Danube, and the Provisional Works erected at the Sulina Mouth.—Sir C. A. Hartley.

ANTHROPOLOGICAL SOCIETY, at 8.—Religious Beliefs of Ojibois or Santeux Indians resident in Manitoba and at Lake Winnepeg: A. P. Reid, M.D.—Danish aspect of the Nomenclature of Cleveland: Rev. J. C. Atkinson.—Rock Inscriptions in Brazil: John Whitfield.

WEDNESDAY, April 23.

LONDON INSTITUTION, at 7.—On some Phenomena connected with Magnetism: W. F. Barrett.

SOCIETY OF ARTS, at 8.—On Silk-Worm Grain: M. Alfred Roland.

ARCHÆOLOGICAL ASSOCIATION, at 8.

SOCIETY OF ANTIQUARIES, at 8.30.—Anniversary.

ROYAL SOCIETY OF LITERATURE, at 8.30.—The Serio Comic Satirical Poetry of the 18th and 19th centuries: Sir Patrick de Colquhoun, Q.C., LL.D.

SOCIETY OF TELEGRAPH ENGINEERS, at 7.30.—On the Block System of Working Railways: W. H. Preece and Capt. Mallock.

THURSDAY, April 24.

ROYAL INSTITUTION, at 3.—Light: Prof. Tyndall.

ROYAL SOCIETY, at 8.30.

THURSDAY, APRIL 24, 1873

SCIENTIFIC ENDOWMENTS AND BEQUESTS

SOME weeks ago we published the notice issued by Trinity College, Cambridge, respecting a Fellowship offered by that corporation for Natural Science, in which Zoology is one of the subjects by which it may be obtained. Candidates are required to send to the electors "any papers which they may have published containing original observations, or experiments, or discussions of scientific questions, or any similar matter in manuscript," and they "will be liable to be examined in the subjects of their papers and in subjects connected with them, or in the branch of science to which they refer."

A fortnight ago, a New York correspondent gave us the details of a munificent bequest made by Mr. John Anderson, a wealthy merchant of that city, to Prof. Agassiz, and through him to the University of Cambridge, Massachusetts, of Penikese Island, situated about 170 miles east by north of New York, and 12 miles south of Boston, on the New England coast, as a station for the study of Practical Zoology, mainly marine. Finding that pecuniary aid was also absolutely necessary to put the whole in working order, Mr. Anderson, with a liberality almost unprecedented, put 50,000 dollars at Prof. Agassiz's disposal, "as a nucleus for a permanent endowment fund" in the formation of his Marine Naturalists' School.

The above-cited cases are two of the most important steps that have been taken of late to advance the thorough study of zoology either in England or America, but the method employed by the one to arrive at this result is so different from that adopted by the other, that the question may well be asked, which of the two in the long run will produce the most satisfactory results? Is it better, as done by Trinity College, to offer considerable and substantial rewards to students of promise, or, as in the case of Mr. Anderson's gift, to simply place undoubtedly great facilities in the way of untried beginners on the subject?

Notwithstanding the extreme liberality shown by Mr. Anderson in his bequest, we cannot help feeling that most of the previous attempts that have been made to advance science by providing increased facilities for work, without at the same time improving the general prospect of a sufficient livelihood for those who devote the whole or the most of their time to it, have met with but little success; and perhaps there is nothing more disappointing to those who are anxious for the progress of the subject, to see the way in which establishments excellently planned at great cost, are often almost at a standstill for want of their most important element—pupils. Such a method of procedure, if numbers are obtained, is likely but to produce an assemblage of amateur students, whose work, as it must be from the lack of sufficient stimulus to great mental effort, is poor from its want of thoroughness, and therefore comparatively useless in the long run, only encumbering the subject and leading lookers-on to suppose, from the few results arrived at, that the science is not worthy of deeper consideration. Zoology and Biology generally have suffered much already from such kind of work.

The tendency of all observation as to the origin and development of the sciences which are now firmly established, is to prove quite clearly that what was required in each of them to give it a start, and make it continue to advance rapidly, was that it should have a practical bearing of some kind or another. There cannot be the least doubt that the rapid advances which have occurred in the study of electricity, and the large number of valuable discoveries and important laws that have been found out concerning it, are but the expression of the mercantile value of the telegraph system as it now exists; the forensic and manufacturing importance of chemistry has in great measure raised it to the important position it now holds; and the money voted for the observations of the transit of Venus is indirectly connected with the importance of astronomical observation in facilitating navigation. But it is not at all easy to show clearly that there are any direct practical results to be arrived at from the study of zoology; the knowledge of the facts that our relationship with the higher apes is more intimate than has been till lately supposed, and that we must consider an Ascidian as the Noah of our zoological pedigree, may be of interest to many as curious results, but they do not lead to or suggest fresh methods of action on the part of anyone, and cannot otherwise be made profitable. Consequently other means must be employed to cause the science to progress in a manner which does credit to the large number of new facts which are continually being brought forward, and the method adopted by Trinity College is one which promises the best results. That the prospect of a Fellowship is a strong inducement to work is undisputed, and what all biologists would like to see, is a little more willingness on the part of other colleges in both Universities, to give them to deserving students of the subject. Some profess to place natural science on the same footing as the other University final examinations, with regard to pecuniary rewards, but it is very seldom, scarcely ever indeed, that we have the opportunity of recording in our columns any elections to natural science fellowships. As long as classics hold the position that they do—one maintained only by the funds and appointments which, but from an excessive and short-sighted conservatism, would have been in great measure diffused in other directions long before now, no complaint can be made of the comparatively non-practical bearing of zoology and comparative anatomy; for though classics may be a good mental training, so is the latter, and the study of the former has certainly not a more practical bearing.

The principle on which the election to the New Trinity Fellowship is to be conducted, is evidently the result of mature consideration and experience, partly no doubt arrived at after the unsuccessful experiment in the same direction a little more than two years ago, in which it was made too evident that a simple examination on the subject could not ensure the discovery of a genuine Zoologist. A much more successful result may be anticipated from the new system of election, for it is difficult to believe that any candidate, who at the time of election has completed sufficient good work to satisfy the electors, can possibly, on account of its intrinsic

interest when he has arrived so far, give up the further pursuit of scientific work. When the governors of any institution can bring men up to this point, and can then supply them with the necessary means, they may consider that their work is finished.

CLERK-MAXWELL'S ELECTRICITY AND MAGNETISM

A Treatise on Electricity and Magnetism. By James Clerk-Maxwell, M.A., F.R.S., Professor of Experimental Physics in the University of Cambridge. (Clarendon Press Series, Macmillan & Co., 1873.)

IN his deservedly celebrated treatise on "Sound," the late Sir John Herschel felt himself justified in saying, "It is vain to conceal the melancholy truth. We are fast dropping behind. In Mathematics we have long since drawn the rein and given over a hopeless race." Thanks to Herschel himself, and others, the reproach, if perhaps *then* just, did not long remain so. Even in pure mathematics, a subject which till lately has not been much attended to in Britain, except by a few scattered specialists, we stand at this moment at the very least on a par with the *élite* of the enormously disproportionate remainder of the world. The discoveries of Boole and Hamilton, of Cayley and Sylvester, extend into limitless regions of abstract thought, of which they are as yet the sole explorers. In applied mathematics no living men stand higher than Adams, Stokes, and W. Thomson. Any one of these names alone would assure our position in the face of the world as regards triumphs already won in the grandest struggles of the human intellect. But the men of the next generation—the successors of these long-proved knights—are beginning to win their spurs, and among them there is none of greater promise than Clerk-Maxwell. He has already, as the first holder of the new chair of Experimental Science in Cambridge, given the post a name which requires only the stamp of antiquity to raise it almost to the level of that of Newton. And among the numerous services he has done to science, even taking account of his exceedingly remarkable treatise on "Heat," the present volumes must be regarded as pre-eminent.

We meet with three sharply-defined classes of writers on scientific subjects (and the classification extends to all such subjects, whether mathematical or not). There are, of course, various less-defined classes, occupying intermediate positions.

First, and most easily disposed of, are the men of calm, serene, Olympian self-consciousness of power, those upon whom argument produces no effect, and whose grandeur cannot stoop to the degradation of experiment! These are the *à priori* reasoners, the metaphysicians, and the *Paradoxers* of De Morgan.

Then there is the large class, of comparatively modern growth, with a certain amount of knowledge and ability, diluted copiously with self-esteem—haunted, however, by a dim consciousness that they are only popularly famous—and consequently straining every nerve to keep themselves in the focus of the public gaze. These, also, are usually, men of "paper" science, kid-gloved and black-coated—with no speck but of ink.

Finally, the man of real power, though (to all seeming) perfectly unconscious of it—who goes straight to his mark with irresistible force, but neither fuss nor hurry—reminding one of some gigantic but noiseless "crocodile," or punching engine, rather than of a mere human being.

The treatise we have undertaken to review shows us, from the very first pages, that it is the work of a typical specimen of the third of these classes. Nothing is asserted without the reasons for its reception as truth being fully supplied—there is no parade of the immense value of even the really great steps the author has made—no attempt at sensational writing when a difficulty has to be met; when necessary, there is a plain confession of ignorance without the too common accompaniment of a sickening mock-modesty. We could easily point to whole treatises (some of them in many volumes) still accepted as standard works, in which there is not (throughout) a tithe of the originality or exhaustiveness to be found in any one of Maxwell's chapters.

The main object of the work, besides teaching the experimental facts of electricity and magnetism, is everywhere clearly indicated—it is simply to upset completely the notion of *action at a distance*. Everyone knows, or at least ought to know, that Newton considered that no one who was capable of reasoning at all on physical subjects could admit such an absurdity: and that he very vigorously expressed this opinion. The same negation appears prominently as the guiding consideration in the whole of Faraday's splendid electrical researches, to which Maxwell throughout his work expresses his great obligations. The ordinary form of statement of Newton's law of gravitation seems directly to imply this action at a distance; and thus it was natural that Coulomb, in stating his experimental results as to the laws of electric and magnetic action which he discovered, as well as Ampère in describing those of his electro-dynamic action, should state them in a form as nearly as possible analogous to that commonly employed for gravitation.

The researches of Poisson, Gauss, &c., contributed to strengthen the tendency to such modes of representing the phenomena; and this tendency may be said to have culminated with the exceedingly remarkable theory of electric action proposed by Weber.

All these very splendid investigations were, however, rapidly leading philosophers away towards what we cannot possibly admit to be even a bare representation of the truth. It is mainly to Faraday and W. Thomson that we owe our recall to more physically sound, and mathematically more complex, at least, if not more beautiful, representations. The analogy pointed out by Thomson between a stationary distribution of temperature in a conducting solid, and a statical distribution of electric potential in a non-conductor, showed at once how results absolutely identical in law and in numerical relations, could be deduced alike from the assumed distance-action of electric particles, and from the contact-passage of heat from element to element of the same conductor.

But we must give Maxwell's own frank and ample acknowledgment of his debt to these two men.

"The general complexion of the treatise differs considerably from that of several excellent electrical works, published, most of them, in Germany, and it may appear that scant justice is done to the speculations of several eminent electricians and mathematicians. One reason of this is that before I began the study of electricity I resolved to read no mathematics on the subject till I had

first read through Faraday's 'Experimental Researches on Electricity.' I was aware that there was supposed to be a difference between Faraday's way of conceiving phenomena and that of the mathematicians, so that neither he nor they were satisfied with each other's language. I had also the conviction that this discrepancy did not arise from either party being wrong. I was first convinced of this by Sir William Thomson, to whose advice and assistance, as well as to his published papers, I owe most of what I have learned on the subject.

"As I proceeded with the study of Faraday, I perceived that his method of conceiving the phenomena was also a mathematical one, though not exhibited in the conventional form of mathematical symbols. I also found that these methods were capable of being expressed in the ordinary mathematical forms, and thus compared with those of the professed mathematicians.

"For instance, Faraday, in his mind's eye, saw lines of force traversing all space where the mathematicians saw centres of force attracting at a distance: Faraday saw a medium where they saw nothing but distance: Faraday sought the seat of the phenomena in real actions going on in the medium, they were satisfied that they had found it in a power of action at a distance impressed on the electric fluids."

It certainly appears, at least at first sight, and in comparison with the excessively simple distance action, a very formidable problem indeed to investigate the laws of the propagation of electric or magnetic disturbance in a medium. And Maxwell did not soon, or easily, arrive at the solution he now gives us. It is well-nigh twenty years since he first gave to the Cambridge Philosophical Society his paper on *Faraday's Lines of Force*, in which he used (instead of Thomson's heat-analogy) the analogy of an imaginary incompressible liquid, without either inertia or internal friction, subject, however, to friction against space, and to creation and annihilation at certain sources and sinks. The velocity-potential in such an imaginary fluid is subject to exactly the same conditions as the temperature in a conducting solid, or the potential in space outside an electrified system. In fact the so-called equation of continuity coincides in form with what is usually called Laplace's equation. In this paper Maxwell gave, we believe for the first time, the mathematical expression of Faraday's *Electro-tonic* state, and greatly simplified the solution of many important electrical problems. Since that time he has been gradually developing a still firmer hold of the subject, and he now gives us, in a carefully methodised form, the results of his long-continued study.

A sentence like the following has a most cheering effect when we meet with it in a preface; and we need only add that our author has been thoroughly successful in the endeavour he promised:—

"I shall avoid, as much as I can, those questions which, though they have elicited the skill of mathematicians, have not enlarged our knowledge of science."

He might with truth, and with propriety, have added that he would also avoid, as far as possible, those so-called experimental illustrations which require in the operator training akin to that of a juggler, and which are calculated to mystify, and to retard the progress of, the real student, while gratifying none but the mere gaping sight-seer.

It is quite impossible in such a brief notice as this to enumerate more than a very few of the many grand and valuable additions to our knowledge which these volumes contain. Their author has, as it were, flown at everything;—and, with immense spread of wing and power of beak, he has hunted down his victims in all quarters, and from each has extracted something new and invigorating—for the intellectual nourishment of us, his readers.

The following points, however, appear to us to be especially (we had almost said exceptionally) worthy of notice:—

1. Though not employing the Quaternion *Calculus*, Maxwell recognises its exceeding usefulness in exhibiting (merely by the extraordinary simplicity and comprehensiveness of its notation) the mutual relations of various directed, or vector, quantities; together with their derivation from scalar quantities, such as potentials, by the use of the Hamiltonian ∇, the operator whose square is the negative of the scalar operator in Laplace's equation. There can be little doubt that in this direction must lie the next grand simplification of the somewhat complex mathematics of electro-dynamic investigations.

2. The notion of electric *Inertia*, first clearly pointed out by Helmholtz and Thomson, is here developed in a most splendid style. The mechanism whose inertia has to be overcome before a steady current of electricity can be started or stopped in a conductor, and which opposes a resistance exactly analogous to the inertia equivalent of an ordinary train of wheels, is treated by means of the general equations of motion in the forms given respectively by Lagrange and by Hamilton. Maxwell has adopted from Thomson and Tait's "Natural Philosophy" the idea of commencing with the impulse required to produce a given motion of a system, and has developed in this way the general equations in a form suitable for electric problems where the mechanism is as yet entirely unknown.

3. The chapter dealing with *Electrolysis* we may specially refer to, as containing, not merely an admirable summary of what was previously known but also, several new ideas apparently of great value.

4. Another curious feature of the work is the amount of labour bestowed upon the exceedingly useful, but dry and uninteresting, pursuit of accuracy in the tracing of the forms of *Lines of Force* and determinations of strengths of electric and electro-magnetic fields, and their deviation from uniformity under various conditions, some of excessive complexity. For the theory of the newer instruments, especially Thomson's electrometers and galvanometers, and also for their applicability to problems in quite different branches of physics, these results are very valuable.

5. Another feature in which this differs from all but a very few of the very best scientific works is the particular care bestowed upon the modes of measurement, the units employed, and the *Dimensions* (in terms of these units) of the various quantities treated of—such as, for instance, Electric Quantity, Electric Potential, Electric Current, Electric Displacement, &c.

6. The subject of *Electric Images* is developed at considerable length, and the reader is led up by easy steps to a sketch of the grand problem which, though solved in simple finite terms a quarter of a century ago by Thomson, has remained unnoticed till very recently, viz., the statical distribution of electricity upon a spherical bowl.

7. The subject of *Spherical Harmonics* (Laplace's coefficients) is also treated at some length, and in a somewhat novel way, which leads to one of the quaternion methods of attack though without actually employing that calculus itself.

8. Further, there is given, for the first time, the complete solution of the problem of *Induction of Currents* in a disc rotating in the magnetic field, taking account of the mutual action of the currents on one another—a condition which very materially increases the difficulty of the problem. The result is a very curious one; and it appears especially curious when we compare the very simple, almost homely, methods employed by Maxwell with the elaborate analysis by means of which Jochmann and others, some years ago, attacked the incomplete and (comparatively) easy statement of the problem where the mutual action of the currents is not taken account of. This piece of work is worthy of being placed beside that of Thomson, referred to under (6) above, as among the very best things ever done in Mathematical Physics.

9. The ratio of the electro-magnetic to the electrostatic unit of electricity is a *Velocity* whose absolute value is independent of the magnitude of the fundamental units employed. This has been shown by Maxwell to be the velocity with which waves of transverse vibration will be propagated in the medium whose stresses &c. account on his theory for the apparent action at a distance. Neither the velocity of light in free space, nor the ratio of the electric units, is *certainly* known as yet within five or six per cent., but it is assuredly a most striking fact that (in millions of metres per second) three of the best determinations of the former of these quantities give

314, 308, 298,

while apparently equally good determinations of the latter give

311, 288, 282.

Such approximation is evidently much more than a mere fortuitous coincidence, it shows that a great step has been taken in the grand question of the connection between radiation and electrical phenomena.

Having said so much in hearty admiration of this noble work, a work which will do more to raise our country in the eyes of really competent judges than cartloads of more pretentious publications, it is only natural to seek some of its defects. There are spots on every sun; and they are, as phenomena, sometimes more instructive and therefore more worthy of observation than the sun itself. But, as they are not visible save to those whose eyes can bear the full glare of the glowing orb, and who therefore do not require our aid, it is unnecessary to point them out. Such a proceeding would be mere pandering to that miserable form of envy which leads inferior minds to gloat over the defects of their superiors.

The concluding section of the work is particularly well fitted to terminate our article.

"We have seen that the mathematical expressions for electrodynamic action led, in the mind of Gauss, to the conviction that a theory of the propagation of electric action in time would be found to be the very keystone of electrodynamics. Now we are unable to conceive of propagation in time, except either as the flight of a material substance through space, or as the propagation of a condition of motion or stress in a medium already existing in space. In the theory of Neumann, the mathematical conception called Potential, which we are unable to conceive as a material substance, is supposed to be projected from one particle to another, in a manner which is quite independent of a medium, and which, as Neumann has himself pointed out, is extremely different from that of the propagation of light. In the theories of Riemann and Betti it would appear that the action is supposed to be propagated in a manner somewhat more similar to that of light.

"But in all of these theories the question naturally occurs:—If something is transmitted from one particle to another at a distance, what is its condition after it has left the one particle and before it has reached the other? If this something is the potential energy of the two particles, as in Neumann's theory, how are we to conceive this energy as existing in a point of space, coinciding neither with the one particle nor with the other? In fact, whenever energy is transmitted from one body to another in time, there must be a medium or substance in which the energy exists after it leaves one body and before it reaches the other, for energy, as Torricelli* remarked, 'is a quintessence of so subtle a nature that it cannot be contained in any vessel except the inmost substance of material things.' Hence all these theories lead to the conception of a medium in which the propagation takes place, and if we admit this medium as an hypothesis, I think it ought to occupy a prominent place in our investigations, and that we ought to endeavour to construct a mental representation of all the details of action, and this has been my constant aim in this treatise."

OUR BOOK SHELF

Medizinische Jahrbücher Herausgegeben, Von der K. K. Gesellschaft der Aerzte redigert von S. Stricker. Jahrgang 1872. Hefte i. ii. iii. iv., pp. 513; mit xii. Tafeln.

THE second volume of Stricker's *Medizinische Jahrbücher*, now before us, maintains the promise of the first. It is made up of a number of separate essays on various subjects, physiological, pathological, and medical; the physiological essays predominating over the others.

Amongst these the following deserve notice.

1. Researches on the heart and blood-vessels, by Dr. Sigismund Mayer. In this paper Dr. Mayer shows that the extraordinary increase of pressure of the blood against the walls of the blood-vessels which occurs as a result of the administration of strychnia is due to intense excitation of the vaso-motor centre in the brain, which leads to contraction of the small arteries.

2. A paper by Ewald Hering on the influence of the respiration upon the circulation. In this he shows that moderate expansion of the lungs by insufflation causes diminished blood pressure in the arteries and increased rapidity of the heart's action. This latter effect, however, is not due to the increased pressure exerted upon the external surface of the heart, nor to alterations in the conditions of resistance in the circulation; nor to differences in the exchange of gases; nor to any dislocation of the heart's position, but is effected reflectorially through the pneumogastrics in such a manner that the activity of the cerebral centre of the inhibitory nerves is lowered.

3. MM. Oser and Schlesinger give the details, in an elaborate essay, of many experiments they have made to determine the causation of the movements of the uterus, and state that they have arrived at the conclusion that these movements can be induced by suspension of the respiration; by rapid loss of blood; or by arrest of the supply of arterial blood to the brain.

4. M. M. Rosenthal contributes an interesting essay on the death of the muscles of the body, and on apparent death. He made many experiments on about twenty sub-

* *Lezioni Accademiche* (Firenze, 1715), p. 25.

jects on the time after death, or rather after the last respiration to show that contraction of the muscles could still be induced by electricity, when applied to them either in the form of the interrupted or of the continuous current. The excitability of the muscles appears to be the same as before death, for a short time after death has taken place; then contractility departing rather sooner in chronic disease than in cases where death has been occasioned by an accident or other sudden event. In most cases contractions may be excited for from $1\frac{1}{2}$ hour to 3 hours after death. The reaction to induced currents falls in a centrifugal direction; the sphincter palpebrarum retaining its irritability longest. From these experiments he was led to think that the absence of irritability in the muscles might be taken as a good means of distinguishing between real and apparent death, and accidentally very shortly afterwards a case of apparent death in an hysterical patient permitted him to satisfy himself as well as others of its value.

5. C. Heitzmann gives the results of his researches on healthy and inflamed bone, and agrees with Rokitansky, that blood is formed in the mother shells that under certain conditions appear in bone.

Other physiological papers are, one by Prof. Bizzozero, of Pavia, on the so-called endogenous formation of cells. Another by Dr. Kolisko, on the mechanics of the heart, and another by Schiff on the round ligament. The papers dealing with therapeutics, are (1) an essay by Dr. Basch on the action of nicotin, especially bearing on the question of the relation of the blood pressure to the periods of rest and contraction of the muscular tissue of the intestines; (2) a number of minor communications from Schroff containing the results of investigations made in the Vienna Pharmacological Institution. The pathological papers of most importance are (1) the remarkable essay of Lostorfer which has led to so much discussion in Germany, in which he declared that he was able to diagnose a certain specific disease (syphilis), by a microscopic examination of the blood; (2) an account by Dr. Philipp Knoll of a case of the rare disease termed paralysis pseudo-hypertrophica; (3) an essay by Dr. J. Popoff on pneumomycosis; (4) investigations on the organisation of thrombus by Dr. Durante; (5) on the changes taking place in ligatured vessels by Dr. Dudokaloff; (6) the diagnosis of disease of the optic thalami. Besides these are several others. The plates are very fairly executed, and our readers will see that Prof. Stricker has done good service in publishing these papers and essays in a collected form.

Reflected and Transmitted Light

[The following correspondence has been sent us by Prof. Tyndall]:—

Cliff House, Greenhithe, April 8

A CURIOUS thing in connection with colour having come under my notice, and never having before seen it remarked in any scientific journal, I take the liberty of bringing it before your notice; if it is new to you it will interest you, if not I must ask you to excuse me for troubling you. On looking through a piece of blue glass (of which I forward you a sample) at a plant or tree lit up by the sun, those leaves that are lit from behind, or rather by transmitted light, appear of a rich crimson, the other leaves, seen only by reflected light, merely take the colour given by the glass. In the case of a geranium plant, those leaves become almost the same colour as the flowers. As a scientific fact, if new, it is curious.

To Prof. Tyndall WALTER B. WOODBURY

THE observation you describe is interesting, and if you have taken care to exclude subjective colouring, is, I should think, to be explained in this way.

The light from your leaves contains a quantity of red: it appears as a yellowish green, I suppose, and contains little or no blue.

Your glass is of a kind which transmits the two ends of the spectrum while cutting out its centre. It is very hostile to the yellow, hence, on placing it before the eye, and receiving through it light which has already been deprived of its blue, the glass quenches the yellow, and red alone remains.

April 9 JOHN TYNDALL

I detained this note until the arrival of sunshine, which enables me to say that the explanation here given is correct. Employing a blue medium, which does not transmit red you get no effect of the kind you describe. The tender leaves of spring are best suited for the experiment: the hard green leaves of ivy, for example, do not produce the effect.

It is not necessary, nor indeed desirable, to have the leaves between the eye and the sun.

April 15

The Zoological Collections in the India House

PERMIT me to offer my testimony in general support of the view taken by P.L.S., in the able article which appeared in your last number. Rather more than a year ago it was a matter of importance for me to examine the type of Horsfield's *Turdus varius*, contained in the Museum of the Old East India Company. I applied in the proper quarter for leave to examine the specimen, but received a polite answer informing me that it was inaccessible. The official statement therefore said to have been made in the House of Commons on March 14, 1871, by the Under-Secretary of State for India, as to the collections being still "available to men of science" is untrue, and I trust that some member of Parliament will not allow this subject to be lost sight of, but, by continually recurring to it, compel the Administration to open their valuable Museum to the public—its owners. To the two solutions of the difficulty suggested by P.L.S., allow me to add a third. If neither the authorities at South Kensington nor in Great Russell Street can properly exhibit the East India Museum, let it be transferred (of course under suitable guarantee), to some other National Institution.

Cambridge, April 22 ALFRED NEWTON

On the Affinities of Dinoceras and its Allies

IN the April number of the *American Journal of Science and Art* there is a paper by Prof. O. C. Marsh, entitled "Additional Observations on Dinocerata," in which we learn that Dinoceras has only four toes. The author still continues to consider the genera *Dinoceras* and *Tinoceras* a separate order intermediate between the Proboscidia and the Perissodactylata. The facts at my disposal are now sufficient for me to state with considerable certainty that *Dinoceras* and *Tinoceras* are members of the Ungulata Artiodactylata. The following are my reasons:—

1. The palate is complete between the posterior molars, as is seen clearly in a photograph of *Tinoceras grandis* (*Loxolophodon cornutus* Cope) in my possession.
2. There is no third trochanter to the femur (Marsh).
3. The astragalus has a well-marked cuboid facet (Marsh).
4. The posterior molar has a small but well developed third cusp, as proved conclusively by an inspection of my photograph.
5. The anterior premolar is wanting, six only being present.
6. The premaxillæ are edentulous
7. There are four toes, an even number.

A. H. GARROD

11, Harley Street, April 22

Auroral Display

A SHORT but very brilliant display of aurora was visible here this evening, making its first appearance soon after sunset, and reaching its greatest intensity between nine and ten o'clock. Some notes of its phases which I was able to make in a perfectly clear sky will perhaps afford useful comparisons with descriptions furnished by observers of its appearance at other places.

The sun had set behind cirrus clouds, surrounded by a slight halo, and with a faint mock-sun on its northern side. As darkness approached, the hazy clouds in the north-west were surmounted by a faint light, and at half-past eight o'clock luminous streaks here and there across the otherwise clear sky, apparently

of cirrostratus cloud, had considerable resemblance to auroral beams faintly visible in the twilight; a considerable extension of the twilight-glow towards the north-west also suggested the very possible character of their light. Towards nine o'clock Mars rose redly through a considerable haze in the east, and Venus, in full splendour, appeared setting among slight clouds in the west; the planet Jupiter, and all stars above a slight distance from the horizon, were altogether unobscured by clouds. A pretty bright white auroral arch, divided into low streamers, was at this time first distinctly formed, its lower edge being well marked by their bases, and the brightest streamers being clustered in two knots of the arch, in the middle of Cassiopeia, and of Lyra, the first immediately under Polaris, and the other close to the north-east horizon; the western prolongation of the arch was faint and diffuse, shining from behind and among the clouds around the planet Venus. Tall but faint streamers rose from it, none of which were conspicuous, excepting a pretty well defined one rising at $9^h\ 5^m$ from the strongly luminous light-cloud in Lyra, nearly to the tail-stars of Ursa Major. This beam grew sharper, and in the following minute it passed across σ Herculis, and ϵ Ursæ Majoris, but it shortly disappeared. Between $9^h\ 8^m$ and $9^h\ 12^m$ the two principal light-clouds in Cassiopeia and Lyra increased in strength, assuming with the contiguous part of the arch a perfect resemblance to the heavy fringe of a curtain gathered or folded upon itself at those points, and particularly in the group of streamers under α Lyræ. At $9^h\ 12^m$ another luminous patch marked the western end of the arch between Venus and Capella, growing brighter, and from it a bunch of rose-coloured streamers sprang upwards between Auriga and Gemini as far as the forefoot of Ursa Major. At $9^h\ 15^m$, the bright cloud-mass marking the eastern horizon-point of the arch under α Lyræ also acquired great strength, throwing up a torch-like, fire-coloured streamer of moderate height and great brightness, terminating the arch abruptly in that direction. It rose from the horizon across o, χ to π, ρ, Herculis. A fainter arch underneath the former one was visible at this time, but less well-defined, and streamers rising from both arches, and mingling together, soon quite overspread the northern sky; a bunch of these streamers of rich crimson colour appeared at $9^h\ 18^m$, extending for a short time across o, θ, and other neighbouring stars of Ursa Major, and fading gradually away, disappeared almost as quickly as it came. The number and sharpness as well as the height of the streamers rising from both the arches were now very great, and the light from all the surrounding streamers was so strong that I could read my watch and correct notes in my note-book at this time. A fourth bunch of red streamers rose from the arch at its extreme west end at $9^h\ 23^m$ from the neighbourhood of α Orionis to the stars γ, ν, in the feet of Gemini. This was the last strikingly red streamer seen during the display; its spectrum, like that of the white beams, which I examined with a small pocket spectroscope, appeared to consist only of the usual bright greenish line, which was very vivid in every phase of the aurora.

At $9^h\ 25^m$, the whole northern half of the sky was covered with streamers, and arches, gradually forming a corona overhead, and increasing rapidly to great intensity and brightness. The boundary of the light from east to west was a definite line passing through, or very little south of the corona, whose centre was 3° or 4° east from the stars ν, χ in Ursa Major. Northwards from the boundary line the aurora consisted of six or seven parallel arches (of which only the lowest two had before been visible), more or less distinctly succeeding each other between the zenith and the horizon. Both the arches and streamers were stationary, and presented no sensible tendency to motion, however slow, while they were visible. At this time the brightening streamers began to flicker in their light. Waves of light, rising from the north, succeeded each other rapidly, and appeared to flow swiftly over them towards the zenith. Arch after arch was visible as the waves passed over them, and fitful gleams among the auroral masses overhead shot to and fro there, like flashes of summer lightning. The rays and wisps of the corona, and belts, or fragments of the aurora overhead were rendered especially luminous by these discharges. Farther from the zenith, in the north, the waves rose smoothly and steadily, with a motion that was indeed very swift, but it was yet quite distinctly discernible, and more easily distinguishable there, than in their passage overhead. The arches, or belts of the streamers appeared to be lighted up instantaneously, as they were reached. Although their inter-mixture in the north made it very difficult to decide this clearly, yet the upward progress of the waves there was very evident, while no such ascending movements could be distinguished in the east and west quarters of the sky. The belts and arches stretching towards those parts of the horizon, through the zenith, and past, or through the corona, forming the termination of the aurora towards the south, were constantly lighted up by momentary flashes, extending almost simultaneously along their whole lengths. The brightness of the flashes in those parts of the aurora which included the corona, and arches or lateral branches extending from it towards the magnetic east and west points is easily accounted for by the belts and clusters of streamers in those positions being seen "on edge," or "end on," extremely foreshortened by perspective, so that the increase of light along their whole heights appeared to be concentrated, when the waves overtook them, to a single flash. The motion of the waves must be extremely swift, as they scarcely occupied more than a second in passing from an altitude of about 45° to the zenith. Supposing that (as the best observations of them have frequently agreed in showing) the heights of auroral arches, and of the bases of auroral streamers, are usually about 100 miles above the earth's surface, the velocity of propagation of these waves of electrical disturbance from north to south cannot have been much less than 100 miles per second. Such a prodigious velocity cannot possibly be ascribed to waves in the upper atmosphere driven by winds among its rarified strata, to which the sweeping motion of the light waves apparently wafted by gusts among the streamers otherwise bore a very singular resemblance.

At $9^h\ 34^m$ some of the strongest waves passing across the corona lighted up a faint white arch in the south, extending from Arcturus across the northern part of Virgo to the head of Leo, several degrees in width. At $9^h\ 37^m$, when the wave disturbance, after continuing in full activity for about ten minutes, ceased as rapidly as it began, this arch and the corona still remained faintly visible; but together with all the other arches and streamers of any altitude lately lighted up by the waves, they soon vanished, and the whole appearance of the sky at $9^h\ 40^m$ was about the same as when the aurora was first seen. At $9^h\ 43^m$, however, the northern sky was again crowded in every part with thin white streamers scattered indiscriminately over it, like groves of slender fir-trees on a hillside, among which one very sharp and bright ray shone for a few seconds, springing from the horizon to a considerable altitude in the west, where it passed across ζ Tauri. At $9^h\ 50^m$ a streamer, starting from a base of intense whiteness near the same place, and tinged at the top with a pinkish hue, ascended across the stars μ, ν, as far as the star ι in Gemini, another very similar streamer almost simultaneous with it, also extended from between Gemini and Auriga to near the forefoot of Ursa Major; a few spots of very intense white light were at the same time visible here and there among the low clouds near the north-west horizon. At $9^h\ 55^m$ all conspicuous streamers had disappeared, leaving only a general glow, among the brighter parts of which the wave disturbance began again, and with less intensity than before, but with the same regularly ascending motions; the undulations succeeded each other without intermission until $10^h\ 5^m$; they then ceased, and the faint appearances of the aurora which were visible after this time were, so far as I could observe them, until half-past eleven o'clock, of a very insignificant and inconspicuous character. The times in this description are from a comparison of my watch with the clock in the Carlisle railway station, and its hand and the figures on its dial being always distinctly visible by the light of the aurora, they have probably been recorded rightly to the nearest minute. Although the dates of the April meteoric shower usually occurring on the nights of the 19th—21st of April are near at hand, I saw but one small shooting-star during the hour of the auroral exhibition. It had a short course in one of the brightest parts of an auroral cloud, and in its light and the aspect of its nucleus it did not appear to be affected in any way remarkably by its passage near or underneath the beams of the aurora.

A. S. HERSCHEL

Carlisle, April 18

April Meteors

DURING the evenings of April 19 (9^h to 11^h) and 20th ($8^h\ 45^m$ to $11^h\ 15^m$) 20 shooting-stars were observed here. The sky was cloudless on both nights, and on the 18th and 19th bright displays of auroræ were noticed. Of the 20 meteors 12 were well observed, and their tracks accurately marked; 8 of

these radiated from near *α* Lyræ, or from a point at R. A. 274°, D. 37 +. The following are the details:—

Date.			Time.		Beginning. R. A.	Beginning. D.	Ending. R. A.	Ending. D.
April 19	...	...	9.28	1st mag. *	295°½	46° +	316°	51° +
,,	...	...	10.31	2nd mag. *	305	38 +	309	37½ +
,,	...	...	10.43	3rd mag. *	277	36½ +	278½	35 +
,,	...	...	10.50	4th mag. *	256½	17 +	254	13 +
April 20	...	...	9.10	3rd mag. *	266	17 +	264½	13 +
,,	...	...	9.50	3rd mag. *	319	45 +	329	45 +
,,	...	...	11.4	2nd mag. *	282	22 +	285	16 +
,,	...	...	11.13	2nd mag. *	264½	16 +	261½	9 +

The other four showed a well-marked radiant point at R. A. 221°½, D. 20 + in Bootes. The observed paths of these were as under:—

Date.			Time.		Beginning. R. A.	Beginning. D.	Ending. R. A.	Ending. D.
April 19	...	...	9.58	2nd mag. *	307°½	43° +	285°	33° +
April 20	...	...	9.9	3rd mag. *	247	28 +	258	29 +
,,	...	...	9.54	1½ mag. *	244	53 +	268	67 +
,,	...	...	10.55	1st mag. *	225	19 +	246	16 +

The brightest meteor seen was one that appeared at $9^h\ 28^m$ on April 20. It diverged from the radiant in Lyra, and was about equal in brilliancy to *α* in that constellation This meteor left a train which remained visible about 1½ sec. after the disappearance of the head.

Bristol, April 21 WILLIAM F. DENNING

I SEND the following observations of the shooting stars of the April period, viz., the 19th and 20th. On the 19th I began to watch at 10^h, but saw no more until 11 45. I then watched them until $3^h\ 15^m$. I found they seemed to come in the region of the heavens about Corona, so I confined my observations to that part as I had not a situation where I could see the opposite side as well By 10 o'clock Hercules was quite above the buildings, so there may have been some meteors visible earlier, when these constellations were too low for me to see. The first night they were all comprised in a triangle, which would be formed by a line stretching from Vega by way of Ophiuchus to Mars, and thence up to Arcturus and by Corona back to Vega. They were pretty equally distributed over this region. The next night they were much more concentrated in Ophiuchus and Hercules and towards Libra. I was not able to determine the radiant, so I confined myself to reckoning them accurately in intervals of fifteen minutes, which time I had conveniently marked for me by the church clocks, and only observed their tracks approximately. On the second night I noted the position and direction of each which shows their concentration about the part named. On the nineteenth there were 25—15 horizontal, 10 vertical. On the 20th from 9.45 to 2.45 there were 33—22 vertical and 11 horizontal. Those I call vertical by distinction were almost all just half way between horizontal and vertical, *i.e.* at an angle of 45°. It was curious how this angle predominated. It was also curious that the first night the horizontal ones predominated, and the second night the vertical. I do not know if I am wrong (1) in assuming that we pass through the node of the orbit of the meteors at this time, and (2) in inferring from this assumption that the angle at which they principally appear to us would be a guide to the inclination of the node. Would the fact of their being horizontal be any proof that the inclination of their orbit is small, and their being vertical a proof that it is much greater, and of a somewhat similar angle? But this would not explain the fact of the majority being horizontal the first night and the majority at a greater angle the next night. One seen on the 20th was intermittent, it ran for a long distance, and became visible at intervals of a few seconds a little way further on. Only a few were of any size, and the first night all but two were extremely small and very faint, with very short tracks. The next night they were not only greater in number but larger, brighter, and with longer tracks. A few left tracks lasting a second or two. One only moved very fast. The first night there was one quite vertical *upwards*. This was the only instance. The majority were from E. to S. or E. to W. on both nights; and the only two of any length on the 19th were one running out of Corona and one running into it. It seemed curious to me how these should be so much longer than all the others and yet lie so close to the point of apparent divergence of them all. The following is a list for the two nights of the number in each 15 minutes: April 19.—From 11.45 to 12, 2; 12.15, 5; 12.30, 2; 12 45, 2; 13, 1; 13.15, 5; 13.30, 1; 13 45, 0; 14, 3; 14.15, 2; 14.30, 0; 14 45, 1; 15, 1; 15 to 15.30, 0; Total: 25.

April 20.—From 9.45 to 10, 1; 10.15, 3; 10 30, 1; 10.45, 0; 11, 5; 11.15, 2; 11.30. 2; 11.45, 1; 12, 0; 12.15, 1; 12.30, 1; 12 45, 1; 13, 2; 13.15. 4; 13.30, 2; 13.45, 2; 13.45 to 14.30. 0; 14.45, 5; Total: 33. P. B.

Bath

Instinct

A Mechanical Analogy

MR. DARWIN, in his article on "The Origin of certain Instincts," in NATURE, of April 3, appears inclined to think that what we may call the instinct of direction in animals is of the same kind as the faculty by which men find their way: and he instances the power of the natives of Siberia to find their way over hummocky ice. He afterwards, however, raises without discussing the question "whether animals may not possess the faculty of keeping a dead reckoning of their course in a much more perfect degree than man, or whether this faculty may not come into play on the commencement of a journey when an animal is shut up in a basket." I wish to point out that this peculiar power of animals is one that cannot be explained as a higher degree of any power that man possesses. What man can do is to find the third side of a triangle after travelling the other two sides *with his eyes open*. Animals can do the same after travelling the two sides *with their eyes shut*. The former power does not in any degree involve the latter. Moreover, the power of man here spoken of depends on the careful use of his powers of observation. This does not appear to be the case with animals. Among the many instances of animals finding their way home after being conveyed away without any opportunity of seeing their way or taking their bearings, there must in all probability be many in which the animal slept on the journey: and if so, the mental or organic process whereby it was able to know its way back must have gone on during sleep. There is nothing in man's mind similar to such a process as this. It can be made conceivable only by a mechanical analogy, if at all.

If a ball is freely suspended from the roof of a railway carriage, it will receive a shock sufficient to move it, when the carriage is set in motion: and the magnitude and direction of the shock thus given to the ball will depend on the magnitude and direction of the force with which the carriage begins to move. While the carriage is in uniform motion the ball will be relatively at rest; and every change in the velocity of the motion of the carriage, and of its direction, will give a shock of corresponding magnitude and direction to the ball. Now, it is conceivably quite possible, though such delicacy of mechanism is not to be hoped for, that a machine should be constructed, in connection with a chronometer, for registering the magnitude and direction of all these shocks, with the time at which each occurred; and from these data—the direction of the shock indicating the direction of the motion of the carriage, the magnitude of the shock indicating its velocity, and the interval of time between two shocks indicating the time during which the carriage has run without change of velocity or direction—from these data the position of the carriage, expressed in terms of distance and direction from the place from which it had set out, might be calculated at any moment. The automatic register of the journey may be conceived as exactly resembling the records of the velocity and direction of the wind produced by one of Robinson's or Beck's self-registering anemometers, where one pencil-mark indicates the direction of the wind, at any past hour, and another its velocity.

Further, it is possible to conceive the apparatus as so integrating its results as to enable the distance and direction of the point where the journey began to the point it has reached, that they can be read off, without any calculation being needed:—a hand on a dial pointing to the direction expressed in degrees of the circle, and the distance being shown in figures expressing miles and decimals of a mile.

Now, I suppose such an integrating process as this (though of course not by any similar mechanism) to be effected in the brain of an animal unconsciously, and that the animal has the power of reading off the result—that is to say, bringing it into consciousness when wanted. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, co. Antrim, April 11

Sense of Orientation

YOUR article on this subject in the issue of March 20, insists very properly on the objection to Mr. Wallace's theory that "if it be solely by the aid of this memory of smells that the dog is

to return to the place whence it was taken, it must needs *make haste* back." I wish to contribute an anecdote of which the hero did not make haste back, and which seems to me to confirm rather the theory already suggested in this correspondence, namely, of a sense of polarity or *orientation* possessed by so many of the lower animals both domesticated and wild. Last summer I was at North Bridgewater, Mass., a shoe-making town about twenty miles south of Boston. At the railroad station I remarked an intelligent dog, whose owner told me, with a good deal of feeling, that he had sold the animal some time previously to be taken to Somerville—a suburb adjoining Boston on the north-west, therefore distant from North Bridgewater at least twenty miles. The dog was carried thither in a closed box-car, probably making a change at Boston, where the railroad terminates. For some two or three weeks the dog made himself at home in his new premises as if perfectly contented, when suddenly he disappeared, and turned up again not at North Bridgewater, the home of his former owner, but at Bridgewater, a mile or two farther south, where he had been raised, at the house of that owner's father; evidently not meaning to be sold again.

I am not sure that it is quite germane to this discussion to call attention to the fact pointed out by the late George Catlin in his "Life amongst the Indians" (p. 96), "that the wild horse, the deer, the elk, and other animals, never run in a straight line: they always make a curve in their running, and generally (but not always) to the left."

"I never have forgotten one of the first lessons that I had from my dear friend Darrow, in deer-stalking in the forest. 'George,' said he, 'when a deer gets up, if the ground is level, never follow him, but turn to the left, and you will be sure to meet him; he always runs in a curve, and when he stops he is always watching his back track.' But *man* 'bends his course;' man, lost in the wilderness or on the prairies, travels in a curve, and always bends his curve to the *left*; why this?"

Of the latter fact Mr. Catlin gives an illustration drawn from his own experience, and adds:

"On arriving at the Sioux village, and relating our singular adventure, the Indians all laughed at us very heartily, and all the chiefs united in assuring me that whenever a man is lost on the prairies he travels in a circle; and also that he invariably turns to the *left*; of which singular fact I have become doubly convinced by subsequent proofs similar to the one mentioned."

New York, April 8 N. Y.

UNITED STATES SIGNAL SERVICE

THE United States Signal Service Bureau has rapidly risen to great and deserved importance. The chief officer, General Albert J. Meyer, is a physician by education, who, during the civil war, was placed at the head of the Signal Corps. In that position he rendered great service, and developed a remarkably complete system of signals. The service now consists of a school of instruction, a central office at Washington, and stations over the country at such points as will enable the observers to note accurately the varying conditions of temperature and the progress of storms. The school is at Fort Whipple, Virginia. "A principal duty of the school has been the drill and instruction of the Observer-Sergeants and the assistant observers for the signal service. In the preparation for these duties each man is required to enlist in the signal detachment at Fort Whipple as a private soldier, and to pass afterwards a preliminary educational examination before he is put under especial instruction. He is then given some knowledge of the theories of meteorology, and is taught the practical use of the various instruments, forms, &c., in vogue at the several stations of observation, while he is practised at the same time in his regular drills of the service. When considered competent he is ordered as an assistant observer to a station where, in addition to perfecting himself in the practical details of the duties at the station, he continues his studies, regularly under the Observer-Sergeant in charge. A service of six months in this capacity renders an assistant eligible as a candidate for promotion. He may then be ordered back to the school to review his studies, and to appear for his final examination before a board of officers appointed for the purpose. Passing this examination, he is promoted to the grade of observer-sergeant, and is considered competent to take charge of a station. This course has been followed successfully during the past year, and each man's fitness has been clearly determined by this probationary service as assistant before his assignment to a more responsible position.

The central office at Washington is in telegraphic communication with all the stations, and each night reports are received at 11 o'clock, P.M., and the results of the digest are telegraphed to all the principal cities in time for the daily morning papers.

From a detailed report of the operations of each of the established stations it appears that during the year there have been issued and distributed at the different lake, sea-coast, and river ports, and in the inland cities a total number of bulletins, maps, &c., as follows:—

Total number of bulletins . . .	187,617
Total number of maps	203,533
Total number of Press reports . .	50,878

The accuracy of the predictions of the Bureau as to the weather changes is stated in the report as follows:—"A comparison of the tri-daily forecasts, or 'probabilities,' as they have been styled, with the meteoric condition afterward reported and, so far as known, has given an average of sixty-nine per cent., as verified up to November 1, 1871. Since that date to the present time (October 1, 1872) the average of verifications has been seventy-six and eight-tenths per cent. If regard be had to those predictions verified, within a few hours after the time for which they were made, this percentage is considerably increased. In view of the deficiency of telegraphic facilities during the year, and the great irregularities of the working, it was not anticipated that these predictions, based as they are upon the tri-daily telegraphic reports, would increase in accuracy. Whatever success has been attained must be considered an indication of what success might be with well organised and full telegraphic facilities."

The number of "cautionary" signals on the inland lakes and on the sea-coast, and their value are thus stated:—"Three hundred and fifty-four cautionary signal orders have been issued during the year, each display of the cautionary signal at any station being considered a separate order. This signal was announced as to be shown 'whenever the winds are expected to be as strong as 25 miles an hour, and continue so for several hours within a radius of 100 miles from the station.' The percentage of the cautionary signals verified by the occurrence within a few hours after the display of the winds described, either at the port at which the signal was exhibited, or within the radius of 100 miles from that port, is estimated to have been about 70 per cent. The instances of signals displayed, reports not verified, are those in which they have not been proven necessary at the station where exhibited. The signal is wholly 'cautionary,' forewarning probable danger. It has been aimed to err on the side of caution. The delays such errors may cause are retrievable—the disasters of shipwreck are not. Since the 1st of July of the present year (1872) thirty-two cautionary signals, forewarning the approach of six different storms, have been displayed at different ports. Of these storms five were destructive, justifying the display of twenty-eight of the signals—one in advance of which four signals were displayed was not considered dangerous."

The operations of the service have been considerably extended by co-operation of the Canadian authorities, and negotiations are in progress designed to furnish signal reports from the West India Islands, and even from Europe.

THE ZOOLOGICAL AND ACCLIMATISATION SOCIETY OF VICTORIA

THE first volume of the Proceedings of this Society, contains upwards of 400 pages, and the prefixed report is altogether very satisfactory. The council of the society

rightly think that Melbourne, from its size and importance, ought to number among its attractions a good zoological collection. If they succeed in obtaining a sufficiently large number of subscribers, they intend, in the first instance, to form as complete a collection as possible of the fauna of Australia, and thereafter, when in a position to do so, to add those of other countries. The Government, we are glad to see, very liberally placed the sum of 1,000*l*. on the estimate for the past financial year.

A considerable amount of success attended the operations of the society during the year previous to March last. A number of pheasants of the silver (*Phaseanus nycthemerus*) and common (*Phaseanus colchicus*) varieties, had been reared, and were to be liberated in suitable places. Upwards of 150 guinea-fowl had been placed in various secluded spots, in forests far removed from settlement, where it is confidently hoped they will increase, and in a few years yield both food and sport.

About 3,500 live trout, hatched at the society's establishment at the Royal Park, Melbourne, had, during the previous season, been placed in different streams. The deer which have been liberated in many parts of the colony are spreading and increasing rapidly, and the society possess a fine collection of six varieties in their grounds at the Royal Park. The valuable stock of Angora goats and the ostriches belonging to the society are thriving and increasing.

Although the society is anxious to encourage and promote sericulture, they find it difficult to advance this industry in a really practical manner so as to be of benefit to the colony. Baron von Mueller has, however, as well as the society, supplied many parts of the colony with white mulberry plants, and when they come into bearing, silk growing will, they hope, become an important industry of the colony.

On account of the services rendered to pisciculture by Sir Robert Officer and Mr. Morton Allpart, of Tasmania, the society have awarded to both these gentlemen their silver medal; their bronze medal has been awarded to Captain Babot, of the *Hydrastes*, for his enterprise in bringing out sea-turtle.

In conclusion, the council are glad to state that the condition of the society is sound and prosperous, and they only require more liberal co-operation from the public to enable them to produce great results in the cause of acclimatisation. We sincerely hope the Australian public will see it to be to their own interest to respond liberally to the desire of the society for assistance in carrying out their benevolent work.

The bulk of the volume is occupied by two papers. The first is a valuable monograph on the "Ichthyology of Australia," by Count F. de Castelnau, in which he gives an account of the different sorts obtainable in the Melbourne fish market: their number is 142. In the introduction the author speaks with great admiration of Dr. Günther's Catalogue of the Fishes in the British Museum, from which he has continually to quote; further on, he criticises that author's views on the distribution of fishes. He also thinks that the learned doctor is too severely condemnatory of the imperfections of his scientific comrades. The second paper is a list by Baron F. v. Mueller of "Select plants readily eligible for Victorian industrial culture."

NEW FRENCH INSTITUTION FOR THE EXPERIMENTAL SCIENCES

AMID all her political turmoil and strife it seems to us a hopeful sign of the real progress of France that she has citizens with energy, enterprise, and enlightenment enough to undertake and carry out a scheme of the magnitude and importance of the one about to be realised at Lyons. It is to be exclusively devoted to scientific research, and the *Revue Scientifique* thinks it deserves to be classed with the richest establishments of a similar kind in England, Germany, and Paris.

For more than a year, it seems, the municipal administrators of Lyons have had it under consideration to form laboratories of physiology and experimental medicine, provided with all the most modern and most approved means of investigation. To settle the plan of such an institution, the muncipality nominated a Commission of scientific men, consisting of MM. Ollier, Perroud, and Tripier. This Commission has given in its report, and the following is the scheme it suggests with regard to the biological sciences alone:—

1. A great central laboratory, equipped for the operations and observations which are required in the experimental study of the physiological and pathological phenomena of the animal economy. In it will be collected and methodically arranged all the instrumental apparatus commonly required for such observations and experiments, especially the registering apparatus.
2. A central hall or store-house of apparatus. This will be the depôt for apparatus and instruments not in daily use, and which are used only in certain circumstances.
3. A laboratory of biological chemistry.
4. A laboratory of biological physics.
5. A laboratory of histology.
6. A room for geological researches relative to the study of parasites and parasitical diseases, including those of the silkworm.
7. A room for autopsies.
8. A room for minute dissections and for the mounting of specimens intended to be preserved.
9. A workshop for construction and repairs, in which will also be set agoing the moving forces intended to work the apparatus.
10. A cabinet of specimens.

11 and 12. A room of design and a small photographic studio.

13. A library.
14. A hall for meetings and lectures.
15. Places for keeping animals.
16. A conservatory and enclosure for researches in vegetable physiology.
17. General offices, houses for the director and assistants, for fuel, water, &c.

The *personnel* comprehends a director and his assistant, a librarian, who will also see to the publication of the works of the establishment, three assistants, one for operations and autopsies, the second for work in biological physics and chemistry, and the third for microscopic studies and work in experimental zoology; finally workmen, laboratory attendants, concierge, groom, &c.

These laboratories are intended for the study of all the branches of the biological sciences, from general and comparative physiology to experimental medicine, questions of hygiene and public health, diseases of animals (especially silkworms), and vegetable physiology.

But, although specially intended as an institution for the biological sciences, the Commission has indicated that the programme would be rendered complete by adding a physico-chemical institute for the study of brute nature, so as to unite in the same establishment the whole body of modern experimental sciences.

On March 7 the Maire of Lyons presented to the Municipal Council a report asking that the scheme be immediately proceeded with. The city of Lyons has presented the grounds of the ancient corn-market on the Quai St. Vincent. According to the plans and estimates of the city architect, the buildings will cost 900,000f., of which this year 330,000f. have been raised. Finally, for the biological sciences alone, a first annual budget of 30,000f. has been set aside.

These figures speak for themselves, and need no comment.

Possession Islands. * From a sketch by Dr. Hooker, C B., F.R.S.

POSSESSION ISLANDS

SEEING is believing. The fitness of Possession Islands for the residence of an observing party during a whole year may be best judged from the accompanying illustration, which is accurately copied from a sketch made by Dr. Hooker at the time a landing was effected. (See NATURE, vol. vii. p. 384.) This was *in midsummer*, and with an exceptionally calm sea. The spot where the crew landed is indicated by an * underneath. A sketch of the place by Captain Davis is given at the beginning of chapter vii. in the first volume of Ross's Voyage.

ON THE ORIGIN AND METAMORPHOSES OF INSECTS*

II.

IN the Coleoptera, the larvæ differ very much in form. The majority are elongated, active, hexapod, and more or less depressed; but those of the Weevils (Pl. 2, Fig 6), of Scolytus, (Pl. 2, Fig. 4), &c., which are vegetable feeders, and live surrounded by their food, as, for instance, in grain, nuts, &c., are apod, white, fleshy grubs, not unlike those of bees and ants. The larvæ of the Longicorns, which live inside trees, are long, soft, and fleshy, with six short legs. The Geodephaga. corresponding with the Linnean genera Cicindela and Carabus, have six-legged, slender, carnivorous larvæ; those of Cicindela. which waylay their prey, being less active than the hunting larvæ of the Carabidæ. The Hydradephaga, or water-beetles (Dyticidæ and Gyrinidæ) have long and narrow larvæ (Pl. 4, Fig. 6), with strong sickle-shaped jaws, short antennæ, four palpi, and six small eyes on each side of the head; they are very voracious. The larvæ of the Staphylinidæ are by no means unlike the perfect insect, and are found in similar situations; their jaws are powerful, and their legs moderately strong. The larvæ of the Lamellicorn beetles (cockchafers, stag-beetles, &c.) feed either on vegetable or on dead animal matter. They are long, soft, fleshy, grubs, with the abdomen somewhat curved, and generally lie on their side. The larvæ of the Elateridæ, known as wireworms, are long and slender, with short legs. Those of the glowworm are not unlike the apterous female. The male glowworm, on the contrary, is very different. It has long, thin, brown wing-cases, and often flies into rooms at night, attracted by the light, which it probably mistakes for its mate.

The metamorphoses of the Cantharidæ are very remarkable, and will be described subsequently. The larvæ are active and hexapod. The Phytophaga (Crioceris, Galeruca, Haltica, Chrysomea, &c.) are vegetable feeders, both as larvæ and in the perfect state. The larvæ are furnished with legs, and are not unlike the caterpillars of certain Lepidoptera.

The larva of Coccinella (the Ladybird) is somewhat depressed, of an elongated ovate form, with a small head, and moderately strong legs. It feeds on Aphides.

Thus, then, we see that there are among the Coleoptera many different forms of larvæ. Macleay considered that there were five principal types.

1. Carnivorous hexapod larvæ, with an elongated, more or less flattened body, six eyes on each side of the head, and sharp falciform mandibles (Carabus, Dyticus, &c.).

2. Herbivorous hexapod larvæ, with a fleshy, cylindrical body, somewhat curved, so that the animal lies on its side (Lucanus, Melolontha).

3. Apod grub-like larvæ, with scarcely the rudiments of antennæ (Curculio).

4. Hexapod antenniferous larvæ, with a subovate body, the second segment being somewhat larger than the others (Chrysomela, Coccinella).

* Continued from p. 446.

5. Hexapod antenniferous larvæ, of oblong form, somewhat resembling the former, but with caudal appendages (Meloe, Sitaris).

The pupa of the Coleoptera is quiescent, and * "the parts of the future beetle are plainly perceivable, being incased in distinct sheaths; the head is applied against the breast; the antennæ lie along the sides of the thorax; the elytra and wings are short and folded at the sides of the body, meeting on the under side of the abdomen; the two anterior pairs of legs are entirely exposed, but the hind pair are covered by wing-cases, the extremity of the thigh only appearing beyond the sides of the body."

In the next three orders, the Orthoptera (grasshoppers, locusts, crickets, walking-stick insects, cockroaches, &c.), Euplexoptera (earwigs), and Thysanoptera, a small group of insects well known to gardeners under the name of Thrips, the larvæ when they quit the egg (Pl. 1 and 2, Figs. 1 and 2) already much resemble the mature form, differing in fact principally in the absence of wings, which are more or less gradually acquired, as the insect increases in size. They are active throughout life. Those specimens which have rudimentary wings are, however, usually called pupæ.

The Neuroptera present, perhaps, more differences in the character of their metamorphoses than any other order of insects. The larvæ are generally active, hexapod, little creatures, and do not differ in appearance so much as those, for instance, of the Coleoptera, but the essential difference is in the pupæ; some groups, as, for instance, the Psocidæ, Termitidæ, Libellulidæ, Ephemeridæ, and Perlidæ, remaining active throughout life, like the Orthoptera; while a second division, including the Myrmeleonidæ, Hemerobiidæ, Sialidæ, Panorpidæ, Raphidiidæ, and Mantispidæ, have quiescent pupæ, which, however, in some cases, acquire more or less power of locomotion shortly before they assume the mature state; thus, the pupa of Raphidia, though motionless at first, at length acquires strength enough to walk, while still enclosed in the pupa skin, which is very thin.†

One of the most remarkable families belonging to this order is that of the Termites, or white ants. They abound in the tropics, where they are a perfect pest, and a serious impediment to human development. Their colonies are extremely numerous, and they attack woodwork and furniture of all kinds, generally working from within, so that their presence is often unsuspected, until it is suddenly found that they have completely eaten away the interior of some post or table, leaving nothing but a thin outer shell. Their nests, which are made of earth, are sometimes ten or twelve feet high, and strong enough to bear a man. One species, *Termes lucifugus*, is found in the South of France, where it has been carefully studied by Latreille. He found in these communities five kinds of individuals—(1) males; (2) females, which grow to a very large size, their bodies being distended with eggs, of which they sometimes lay as many as 80,000 in a day; (3) a kind described by some observers as Pupæ, but by others as neuters. These differ very much from the rest, having a long, soft body without wings, but with an immense head, and very large, strong jaws. These individuals act as soldiers, doing apparently no work, but keeping watch over the nest and attacking intruders with great boldness. (4) Apterous, eyeless individuals, somewhat resembling the winged ones, but with a larger and more rounded head; these constitute the greater part of the community, and like the workers of ants and bees, perform all the labour, building the nest and collecting food. (5) Latreille mentions another kind of individual which he regards as the pupa, and which resembles the workers, but has four white tubercles on the back, where the wings will afterwards make their appearance There is still, however, much difference of opinion among entomologists, with reference to the true nature of these different classes of individuals. M. Lespés, moreover, who has recently studied the same species, describes a second kind of male and a second kind of female. The subject, indeed, is one which offers a most promising field for future study.

Another interesting family of Neuroptera is that of the Ephemeræ, or mayflies (Pl. 3, Fig. 1), so well known to fishermen. The larvæ (Pl. 4, Fig. 1) are semi-transparent, active, six-legged little creatures, which live in water, and having at first no gills, respire through the general surface of the body. They grow rapidly and change their

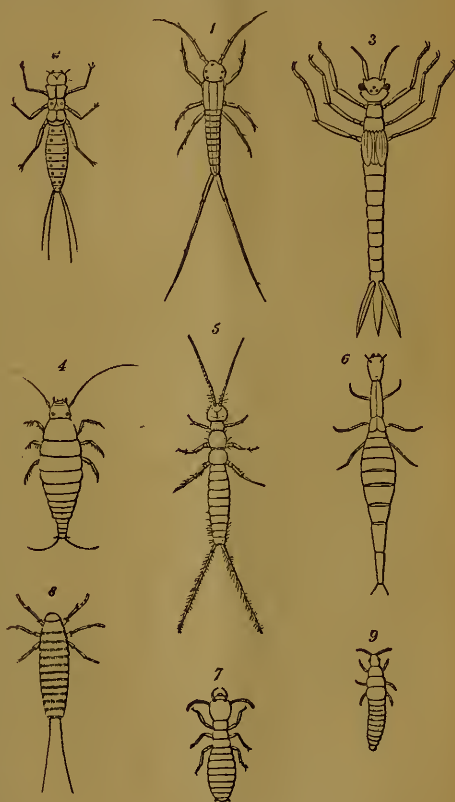

PLATE 4

PL. 4.—FIG. 1, Larva of Chloeon. 2, Larva of Meloe (after Chapuis Candeze). 3, Larva of Calepteryx (after Leon Dufour). 4. Larva of Sitaris 5, Larva of Campodea (after Gervais). 6, Larva of Acilius 7. Larva of Termes (after Blanchard) 8, Larva of Stylops. 9, Larva of Thrips.

skin every few days. After one or two moults they acquire seven pairs of branchiæ, or gills, which are in the form of leaves, one pair to a segment. When they are about half grown, the posterior angles of the two posterior thoracic segments begin to elongate. These elongations become more and more marked with every skin. One morning, in the month of June, some years ago, I observed a full-grown larva, which had a glistening appearance, owing to the pre-

* Westwood's Introduction, vol. i. p. 36. † Ibid. vol. ii. p. 53.

sence of a film of air under the skin. I put it under the microscope, and then, having added a drop of water with a pipette I put the instrument down and looked through the glass. To my astonishment, the insect was gone, and an empty skin only remained. I then caught a second specimen, in a similar condition, and put it under the microscope, hoping to see it come out. Nor was I disappointed. Very few moments had elapsed, when I had the satisfaction of seeing the thorax open along the middle of the back; the two sides urned over; the insect literally walked out of itself, unfolded its wings, and in an instant flew up to the window. Several times since, I have had the pleasure of witnessing this wonderful change, and it is really extraordinary how rapidly it takes place; from the moment when the skin first cracks, not ten seconds are over before the insect has flown away.

The Dragon-flies, or Horse-stingers, as they are sometimes called, from a mistaken idea that they sting severely enough to hurt a horse, though in fact they are quite harmless, also spend their early days in the water. The larvæ are brown, sluggish, ugly creatures, with six legs. They feed on small water animals, for which they wait very patiently, either at the bottom of the water or on some water plant. The lower jaws are attached to a long folding rod, and when any unwary little wretch approaches too near the larva, this apparatus is shot out with great velocity, and the prey which comes within its reach seldom escapes. In their perfect condition, also, Dragonflies feed on other insects, and may often be seen hawking round ponds. The so-called Ant-lion in many respects resembles the Dragon-flies, but the habits of the larvæ are very dissimilar. They do not live in the water, but prefer dry places, where they bury themselves in the loose sand, and seize any little insect which passes, with their long jaws. The true Ant-lion makes itself a little pit in loose ground or sand, and buries itself at the bottom. Any inattentive little insect which steps over the edge of this pit immediately falls to the bottom, and is instantaneously seized by the Ant-lion. Should the insect escape and attempt to climb up the side of the pit, the Ant-lion is said to throw sand at it, knocking it down again.

One other family of Neuroptera I must mention, the Hemerobiidæ. The perfect insect is a beautiful, lacewinged, very delicate, green insect, something like a tender Dragonfly, and with bright green, very touching eyes. The females deposit their eggs on plants, not directly on the plant itself, but attached to it by a long white slender footstalk. The larvæ have six legs and powerful jaws, and make themselves very useful in destroying the Hopfly.

The insects forming the order Trichoptera are well known in their larval condition, under the name of caddis worms. These larvæ are not altogether unlike caterpillars in form, but they live in water—which is the case with very few lepidopterous larvæ—and form for themselves cylindrical cases or tubes, built up of sand, little stones, bits of stick, leaves, or even shells. They generally feed on vegetable substances, but will also attack minute freshwater animals. When full grown, the larva fastens its case to a stone, the stem of a plant, or some other fixed substance, and closes the two ends with an open grating of silken threads, so as to admit the free access of water, while excluding enemies. It then turns into a pupa, which bears some resemblance to the perfect insect, "except that the antennæ, palpi, wings and legs are shorter, enclosed in separate sheaths and arranged upon the breast." The pupa remains quiet in the tube until nearly ready to emerge, when it comes to the surface, and in some cases creeps out of the water. It is not therefore so completely motionless as the pupa of Lepidoptera.

The Diptera, or Flies, comprise insects with two wings only, the hinder pair being represented by minute clubshaped organs called halteres. Flies quit the egg generally in the form of fat, fleshy, legless grubs. They feed principally on decaying animal or vegetable matter, and are no doubt useful as scavengers. When full grown they turn into pupæ which are generally inactive; those of some gnats, however, swim about. Other species, as the gadflies, deposit their eggs on the bodies of animals, within which the grubs, when hatched, feed. The mouth is generally furnished with two hooks which serve instead of jaws. The pupæ are of two kinds. In the true flies, the outer skin of the full-grown larva is not shed, but contracts and hardens, thus assuming the appearance of an oval brownish shell or case, within which the insect changes into a chrysalis. The pupæ of the gnats, on the contrary, have the limbs distinct and enclosed in sheaths. They are generally inactive, but some of the aquatic species continue to swim about.

One group of Flies, which is parasitic on horses, sheep, bats, and other animals, has been called the Pupipara, because it was supposed that they were not born until they had arrived at the condition of pupæ. They come into the world in the form of smooth ovate bodies, much resembling ordinary dipterous pupæ, but as Leuckart has shown,* they are true, though abnormal, larvæ.

The next order, that of the Aphaniptera, is very small in number, containing only the different species of Flea. The larva is long, cylindrical, and legless; the chrysalis is motionless, and the perfect insect is too well known, at least as regards its habits, to need any description.

Unlike the preceding orders of insects, the Heteroptera quit the egg in a form, differing from that of the perfect insect principally in the absence of wings. The species constituting this group though very numerous, are generally small, and not so familiarly known to us as those of the other large orders, with indeed one exception, the well-known Bug. This was not, apparently, an indigenous insect, but seems to have been introduced. Shakespeare uses the word several times, but always in the sense of a bugbear, and not with reference to this insect. In this country it never acquires wings, but is stated to do so sometimes in warmer countries. The Heteroptera cannot exactly be said either to sting or bite. The jaws, of which, as usual among insects, there are two pairs, are like needles, which are driven into the flesh, and the blood is then sucked up the lower lip, which has the form of a tube. This peculiar structure of the mouth prevails throughout the whole order; consequently their nutriment consists almost entirely of the juices of animals or plants. In their metamorphoses the Heteroptera resemble the Orthoptera; they are active through life, and the young resemble the perfect insects except in the absence of wings, which are gradually acquired. The majority are dull in colour, though some few are very beautiful. The Homoptera agree with the Heteroptera in the structure of the mouth, and in the metamorphoses. They differ principally in the front wings, which in Homoptera are membranous throughout, while in the Heteroptera the front part is thick. As in the Heteroptera, however, so also in the Homoptera, some species do not acquire wings. The Cicada, so celebrated for its song, and the lanthorn fly, belong to this group. So also does the so-called Cuckoospit, so common in our gardens, which has the curious faculty of secreting round itself a quantity of frothy matter which serves to protect it from its enemies. But the best known insects of this group are the Aphides, or Plant-lice; while the most useful belong to the Coccidæ, or scale insects, from one species of which we obtain the substance called lac, so extensively used in the manufacture of sealing-wax and varnish. Several species also have been used in dyeing, especially the Cochineal insect of Mexico, a species which lives on the Cactus. The male Coccus is a minute, active insect, with four comparatively large wings, while the female, on the contrary, never acquires wings,

* Die Fortpflanzung und Entwickelung der Pupiparen. Von Dr. R. Leuckart. (Halle, 1848.)

but is very sluggish, broad, more or less flattened, and, in fact, when full grown, looks like a small brown scale.

The larvæ of Lepidoptera are familiar to us all, under the name of caterpillars. The insects of this order in their larval condition are almost all phytophagous, and are very uniform both in structure and habits. The body is long and cylindrical, consisting of thirteen segments; the head is armed with powerful jaws; the three following segments, the future prothorax, mesothorax, and metathorax, bear three pairs of simple articulated legs. Of the posterior segments, five also bear false or pro-legs, which are short, unjointed, and provided with a number of hooklets. A caterpillar leads a dull and uneventful life; it eats ravenously, and grows rapidly, casting its skin several times during the process, which generally lasts only a few weeks, though in some cases, as for instance the goat-moth, it extends over a period of two or three years, after which the larva changes into a quiescent pupa or chrysalis.

JOHN LUBBOCK

(To be continued.)

ON THE STRUCTURE OF STRIPED MUSCULAR FIBRE

A HIGHLY interesting paper on the above subject was read before the Royal Society on April 3, by Mr. E. A. Schäfer, of University College. The muscle of the limbs of the large water-beetle formed the subject of the investigation, and it was examined immediately after removal from the living animal, without the addition of any reagent, to prevent the introduction of complications. According to the author, a muscular fibre consists of a homogeneous ground substance, which appears at first sight to be formed of two distinct substances, one dim and the other bright, arranged in alternate discs at right angles to the direction of the fibre; and a vast number of minute rod-like bodies, imbedded in the protoplasmic basis, having their axes coincident with that of the fibre itself. These are termed *muscle rods*; in the muscle at absolute rest they are uniformly cylindrical, and produce the appearance of a simple longitudinal fibrillation in the fibre, with no transverse striping. But when in action these muscle-rods are terminated at each extremity by a knob, and are consequently dumb-bell shaped. It is these knobs which give the appearance of the line of dots which is always described as existing in the middle of each bright transverse band of the muscle fibre, whereas the dim one is that in which the shafts of the muscle-rods are imbedded. In contraction of the muscle, the heads of the rods become enlarged at the expense of the shafts, the extremities of each muscle-rod consequently approaching one another; and the enlarged heads come nearer to their neighbours of the same series, and to those of the next series which meet them in the bright stripe, the line of dots now appearing as a dark transverse band with bright borders. As contraction proceeds the shaft of the muscle-rod tends to, and ultimately disappears, leaving an appearance of alternate dark and light stripes; the former however are in this case due to the enlarged juxtaposed extremities of the rods, the latter on the other hand being mainly due to the accumulation of the ground-substance in the intervals between their shafts. An examination of minute oil-globules imbedded in gelatine shows clearly that they give the appearance under the microscope of dark spots with a brilliant surrounding, and several side by side produce the effect of a bright band. From many considerations it can be shown that the bright transverse bands in muscle are similarly produced by the juxtaposition of the rod-heads, among which are the following:—1. When the rod-heads are smaller the bright bands are narrower. 2. When the rod-heads have become merged with the shafts in full contraction, the bright transverse stripes entirely disappear. 3. When in contraction the rod-heads enlarge and encroach on the shaft, their bright borders accompany them and encroach on the dim substance, so that at last all appearance of dimness becomes entirely obliterated, the bright borders becoming blended in the middle. 4. The part of the muscle-rod where the head joins the shaft, is rendered indistinct by the brightness around the rod-head; whereas if this brightness were inherent in the ground substance, this part of the rod would stand out all the darker by the contrast. 5. The appearance of a transverse section is corroborated; for in this case the rod-heads are seen so close together that the optical effect of any one would become merged into those of its neighbours: consequently the whole of the intermediate substance would appear bright; and this is actually found to be the case. 6. The fact that both the dim and the bright substance of resting muscle appear doubly refracting, would indicate that they are of the same nature.

Mr. Schäfer with polarised light has found that *all* the ground-substance of the fibre is doubly refractive, the rods alone being singly refractive. He concludes the paper by offering a conjecture as to the mode of muscular contraction, in which he is inclined to regard the ground-substance as the true contractile part, and the rods as elastic structures, merely serving to restore the fibre to its original length.

NOTES

A RUMOUR as to the fate of Sir Samuel and Lady Baker, of a kind similar to those which have ever and anon filled the air with reference to the undying Livingstone, appeared in the *Times* of Thursday last. At the end of last year, with his force dwindled down to 200 men, Sir Samuel had penetrated south until he had reached the territory of the chief of the tribes squatting near the great lakes, who had hitherto been friendly to the Egyptian government. His reception of Baker and his companions was however the reverse of friendly. Whatever the cause, a desperate conflict with the natives ensued, and after much hard fighting, Baker was compelled to retreat with but 30 out of his 200 men. It was with the utmost difficulty that the survivors succeeded in intrenching themselves in a small fort, whence to beat back further attacks. Such, according to report, was the state of matters at the end of last year. The present rumour is that Sir Samuel and Lady Baker having at last been compelled to surrender, were immediately afterwards murdered. A telegram from H.M. Consul at Alexandria, dated the afternoon of last Thursday, announces that no intelligence of any sort respecting Sir Samuel and Lady Baker had been received by the Egyptian Government, or by any other, since March 5 last. A telegram of April 19, from the Alexandria *Daily News* Correspondent states that the rumour seems to be utterly unfounded. We have, moreover, been assured by one who has the best opportunities of knowing, that no news has really been received, and that the reports about Sir Samuel are inventions: "there is not," he writes us, "a word of truth in them."

WE regret to announce that Baron Liebig's illness, to which we referred last week, has terminated in death. The great chemist died on the 18th instant, aged nearly 70 years, having been born at Darmstadt on May 12, 1803. His funeral took place with great ceremony at Munich on the 21st. We hope, in an early number, to be able to give a memoir of the late Baron.

IT is with the greatest regret that we announce the death, on the 20th inst., after a long, and latterly, severe illness, of Dr. Bence Jones, Secretary to the Royal Institution, the efficiency of which he has done much to promote. Dr. Jones was a distinguished chemist, and among his contributions to the advancement of science may be mentioned his Croonian Lectures on Matter and Force, Animal Chemistry in relation to Stomach and

Renal Diseases, Lectures on Pathology and Therapeutics, &c. His reputation has been latterly much extended by his work on the early history of the Institution, and by his excellent biography of Faraday. Dr. Jones was a member of many learned and scientific societies, at home and abroad. It will not be easy for the managers of the Royal Institution to find one capable of so efficiently discharging the duties of Secretary. Our readers will remember that a short time ago a movement was set on foot to get up a well-deserved testimonial to Dr. Jones, which, in agreement with his own wishes, is to take the form of a bust to be placed in the Royal Institution.

DR. F. ARNOLD LEES and Mr. T. B. Blow propose to form a club under the name of the Botanical Locality Record Club, the object of which shall be to collect and keep a record of the exact localities of all the rarer British plants, with the dates of the latest observance of each, to be published yearly at the end of each season. The yearly report, containing not only a detailed list of the localities, but also a geographical summary of each year's work, is to be published and distributed only to members of the club, and to certain learned societies; to the former a subscription of 5*s*. will be charged. The names of botanists desiring to become members are to be forwarded to Mr. T. B. Blow, Welwyn, Hertfordshire.

MR. N. HOLMES, Curator of the Museum of the Pharmaceutical Society, has been appointed Lecturer on Botany to the Westminster Hospital, in the place of Mr. A. W. Bennett.

DR. ACLAND, the Regius Professor of Medicine in the University of Oxford, has given notice that the following gentlemen have been appointed to Radcliffe Studentships for the ensuing Term: Mr. A. W. Harding, of University College Hospital; Mr. Joseph H. Philpot, of King's College Hospital; Mr. William Garton, of St. Thomas's Hospital; and Mr. Frederick W. Jordan, of the Manchester Infirmary.

AMONG the works recommended by the Board of Studies in Natural Science of the University of Oxford to students preparing for examination at the University, is Sachs's "Lehrbuch der Botanik." For the benefit of those unacquainted with the German language, the Delegates of the Clarendon Press have arranged with Prof. Sachs and with MM. Engelmann, of Leipzig, for an English translation of this work from the third edition, just published in Germany, and containing a large amount of additional matter; the whole of the 460 woodcuts with which the original work is illustrated will be reproduced in the English edition. The translation has been entrusted to Mr. A. W. Bennett, who will also annotate the work on points where sufficient prominence does not appear to be given to recent researches, or undue prominence seems to be asssigned to certain theories, in which part of the labour he will be assisted by Prof. Thiselton Dyer. The work is expected to be ready by about the end of the year.

THE Edinburgh Botanical Society offers a prize of ten guineas for the best and approved essay on the Reproduction of Lycopodiaceæ, to be competed for by students who have attended the botanical class of the Royal Botanic Garden, Edinburgh, during at least one of the three years preceding the award, and have gained honours in the class examinations. The author is expected to give results of practical observations and experiments made by himself on the subject, illustrated by microscopical specimens. The essay and specimens to be given in on or before May 1, 1876, with a sealed note containing the author's name, and a motto outside. Facilities will be given for carrying on observations and experiments at the Royal Botanic Garden, Edinburgh. A prize of ten guineas is offered, through the Council of the Botanical Society, by Charles Jenner, Esq., for the best and approved essay on the Structure and Reproduction of the Frondose and Foliaceous Jungermanniaceæ. This prize is subject to all the conditions specified in the case of the former.

MR. CHARLES B. PLOWRIGHT, of the Hospital, King's Lynn, proposes issuing, under the title of "Sphæriacei Britannici," a few sets, each containing one hundred specimens, intended to form a fair representation of the more important genera and species of the British Sphæriacei. The price will be 1*l*.

THE soirée of the Royal Society is to take place at Burlington House on Saturday evening next, the 26th inst.

WE regret to announce the death of Sir William Tite, M.P., at Torquay, on Sunday.

WE regret to hear of the serious illness of the Rev. George Henslow from a paralytic seizure, which has impaired the use of the lower limbs, but has not in any way affected his mental faculties, or the use of his arms. We understand that he has appointed Dr. B. T. Lowne to take his place for the present season as lecturer on Botany at Bartholomew's Hospital.

IN pursuance of the recommendation of a committee appointed at a former meeting, a conference, presided over by the Rev. H. Solly, took place on Saturday evening in further promotion of the movement for giving some of the advantages of University education to working men. The idea is to form a Guild of Operative tradesmen to arrange for the delivery of lectures in various places by lecturers provided by and sent from the University of Cambridge. Mr. Solly stated what had been done since last meeting. The Council of Trades' Delegates had passed a resolution expressing great satisfaction with the progress of the proposed scheme, while in the interviews which the chairman had had with the heads of the University every encouragement had been afforded to the project, provided that a firm organisation could be secured to deal with. The following resolution was passed:—"That, in the present defective state of technical and higher education for the workman, no adequate provision being made for those objects, either by the State or by private endeavour, this meeting hails with satisfaction the proposal to form a Trades' Guild of Learning to co-operate with the University of Cambridge and other parties willing to aid in the education of the people."

FREDERICH DAUTWITZ writes us that he will exhibit a collection of *Cactaceæ* at the Lustschloss, Schönbrunn, Vienna, where he will be glad to receive visitors. He is also desirous of effecting exchanges.

THE sum which was left as the proceeds of Prof. Tyndall's lectures in America, after paying expenses, was 13,000 dols. This balance has been placed in charge of a committee consisting of Prof. Henry, General Hector Tyndale (Prof. Tyndall's cousin), in Philadelphia, and Prof. Youmans, of New York, and these gentlemen are authorised to expend it in aid of students who devote themselves to original investigation. A suggestion has been made, and one worthy of encouragement, that efforts be initiated to secure an increase of this fund to at least 50,000 dols., the whole to bear the name of the Tyndall Fund, so that the objects of the professor may be carried out to a fuller extent.

SCIENCE is certainly in the ascendant in America at present. A fortnight ago we noted the princely gift of Mr. Anderson to Prof. Agassiz. The California Academy of Sciences has recently received from Mr. James Lick a magnificent gift of a building site in the city of San Francisco, valued at about 100,000 dollars.

FOR the purpose of more fully carrying out the law of Congress in reference to the propagation of useful food fishes in the rivers

and lakes of the United States, the United States Commissioner of Fish and Fisheries made arrangements with Mr. N. W. Clark to hatch out several hundred thousand white fish eggs at his establishment at Clarkston, Michigan, with the special object of transferring them, in due season, to the waters of California. At the proper time, in February last, two hundred thousand eggs were carefully packed and forwarded to California; but, for some unexplained reason, they were nearly all dead on their arrival. In no way discouraged by this experience, the Commissioner directed the shipment of a second lot of two hundred thousand eggs, which arrived in good condition, and the greater number have since hatched out at the State hatching establishment at Clear Lake, into which body of water they will be put at the right time. The feasibility of shipping the eggs of white fish over so great a distance has now been satisfactorily solved, and there will probably be no difficulty in carrying on this work to any desirable extent. Mr. Stone has returned to the East with the view of procuring living black bass, eels, perch, and lobsters, which he will take back to California in a few weeks, in a special car arranged expressly for the purpose. The California Commissioners appear to be fully alive to the interests involved in the multiplication of the food-fishes in their State, and seem disposed to leave no method untried to accomplish this desirable object.

THE American Association for the Advancement of Science commences its twenty-second session at Portland, Maine, on Aug. 20.

THE Annual General Meeting of the Iron and Steel Institute will be held at Willis's Rooms, London, on April 29 and 30, and May 1.

PROF. O. C. MARSH has in the current number of the *American Journal of Science and Ars* done much to clear up the difficulties connected with the *Dinocerata*. He has had the opportunity of comparing his specimens with photographs of *Eobasileus* or *Loxolophodon cornutus* of Cope, for the first time, and finds that it is exactly the same as the species named by him (Marsh) *Tinoceras grandis* some time before the introduction of either of Prof. Cope's synonyms. Prof. Marsh says, "The species of *Dinocerata* at present known with certainty are the following:—*Tinoceras anceps* Marsh, *Tinoceras grandis* Marsh, *Uintatherium robustum* Leidy, *Dinoceras mirabilis* Marsh, *Dinoceras lacustris* Marsh." With regard to the osteology of the class, we are surprised to hear for the first time that in the foot the hallux is absent, and the astragalus articulates with the cuboid as well as the naviculare bone, features not Proboscidian at all.

IF we may judge from the "Register" of Lehigh University, South Bethlehem, Penns., U.S., that institution seems to be, in most respects, a model one. It was founded only a few years ago, and is the result of a magnificent gift of 500,000 dollars and 56 acres of ground, beautifully situated in the Lehigh Valley, South Bethlehem, by the Hon. Asa Packer. South Bethlehem is about fifty-four miles from Philadelphia. The education given by the staff of professors is free, the only expense to the student being his board, books, apparatus, &c. According to the plan of education laid down, the first three terms "are devoted, by all regular students, to the study of those elementary branches in which every young man should be instructed, for whatever profession or business in life he may be intended, viz, Mathematics, Languages, Elementary Physics, Chemistry, Drawing, History, Rhetoric, Logic, Declamation, and Composition." At the end of this preliminary period, by which time the Lehigh student will be not less than 17½ years old, he makes up his mind what particular direction his studies will take during the remaining five terms (2½ years) which complete the regular course. According as he decides, the student goes through the special course provided for one of the following subjects:—General Literature, Civil Engineering, Mechanical Engineering, Mining and Metallurgy, or Analytical Chemistry: three other departments have yet to be added to this special course. According to the prospectus before us, the training provided in each of the special courses is wise and thorough, and well calculated to put a diligent student in the way to make the furthest advances in the branch he adopts. Any student who wishes may pursue his studies at the University free for three years longer than the regular course. Latin and Greek are optional in all departments except that of Literature (which, by the bye, has a large infusion of physical science), while French and German are imperative in all. The institution is rendered complete by an excellent laboratory, a well-furnished observatory and a gymnasium.

PROF. PETERS has named the last two planets discovered by him, Nos. 129 and 130, Antigone and Electra.

AMONG Mr. Murray's list of forthcoming works are the following:—"The evil Effects of Interbreeding in the Vegetable Kingdom," by Charles Darwin, F.R.S.; Sir Charles Lyell's "Antiquity of Man," 4th edition; "England and Russia in the East," by Sir Henry Rawlinson, K.C.B., F.R.S.; "Human Longevity: its Facts and Fictions," by W. J. Thoms; "Personal Recollections from Early Life to Old Age," by Mary Somerville.

THE Perthshire Society of Natural Sciences has recently done a very proper thing. On the suggestion of the council, the Hon. Secretary was instructed to communicate with such members of the Society as might be elected to serve on the Perth School Board and other School Boards in Perthshire, and ask them to keep in view the importance of introducing into the course of instruction in schools the elements of natural science.

SOME time since a paragraph appeared in NATURE relating to a supposed power of a preparation of boxwood over the growth of the human hair. A correspondent would be glad if any of our readers could inform him in what way the preparation is made, and what part of the plant is used.

MR. F. W. PUTNAM has sent us a few archæological notes on an ancient fortification surrounded by a great number of mounds, at Merom and Hutsonsville, Sullivan Co., Ind., U.S. The fort is situated on a plateau of loess, about 170 feet above the Wabash, on the east bank of the river. The position of the fort would be one of great advantage even at the present day. One of the mounds outside was dug into, and at the bottom of the pit thus made were found remains of a fire, bones of animals, pottery, and an arrow head. Mr. Putnam concludes that the pits now filled up so as to form mounds, were the houses of the inhabitants or defenders of the fort.

THE additions to the Zoological Society's Gardens during the last week include an Ocelot (*Felis pardalis*), from Honduras, presented by Miss E. E. Brooks; two vinaceous Turtle Doves (*Turtur vinaceus*) from W. Africa, presented by T. P. Tindale; a Leopard (*Felis pardus*) and a Civet Cat (*Viverra civetta*) from W. Africa, presented by L. Hart; two Goldfinch (*Carduelis elegans*) and two Canary Finches (*Serinus canarius*) from Madeira, and a Paradise Whydah Bird (*Vidua paradisea*) from W. Africa, presented by Lieut. F. L. C. Hearne; a Philantomba Antelope (*Cephalopus maxwellii*), born in the Gardens; three Indian Tree Ducks (*Dendrocygna arcuata*); three Summer Ducks (*Aix sponsa*) from N. America; two Hooded Cranes (*Grus monachus*) from Japan, purchased; two Malayan Tapirs (*Tapirus indicus*), a Rhinoceros Hornbill (*Buceros rhinoceros*), from the Malay peninsula; a Derbian Wallaby (*Halmaturus derbianus*) from Australia; a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama; and a Greater Sulphur Crested Cockatoo (*Cacatua galerita*) from Australia, deposited.

THE BIRTH OF CHEMISTRY

IX.

Early Ideas concerning the Process of Combustion.—Association of Nitre with the Air, so far as the part they play in Combustion is concerned.—Hooke's Theory of Combustion.—Mayow's Experiments.—Early Pneumatic Chemistry.—Proof of the Analogy existing between Combustion and Respiration.

AS in the history of matter we find molecules grouping themselves around a common centre or a common line, thus constituting crystalline bodies, so in the history of sciences and of nations we may often observe well-defined axes, about which the facts of particular epochs congregate. Such axes are to be found in the history of chemistry. At the particular period of which we now write, the facts of the science mainly grouped themselves around theories connected with combustion, which involved as collateral matters conceptions regarding the nature of calcination, and of the air.

Combustion was, and still is, the most prominent exhibition of chemical force, with which man ordinarily comes into contact. It is a purely chemical action—the union of dissimilar bodies under the influence of chemical affinity, attended by the evolution of light and heat. Many attempts were made to explain its cause. Fire, in common with earth, air, and water, as we have before seen, was regarded as an element, till almost within our own memory. Epicurus regarded heat as a congeries of minute spherical particles possessing rapid motion, and readily insinuating themselves into the densest bodies. Fire was simply an intense form of heat. Cardanus speaks of flame as *aer accensus*, and of fire as heat immensely augmented. During the Middle Ages the existence of two kinds of fire was admitted—the one pure celestial fire "*subtilis ignis*," "*cœlestis ignis*," the principle or essence of fire; the other "gross earthly fire," or "mundane fire." The latter was the *materia*, the former the *forma*. Celestial fire became mundane fire when it was associated with combustible bodies, that is, in ordinary combustion. Seneca tells us that the Egyptians divided each element into an active and a passive form; fire became active flame which burns, and comparatively passive warmth and light. The elemental nature of fire was not universally admitted during the Middle Ages; thus Francis Bacon asserts, in the *Novum Organum*, that fire is "merely compounded of the conjunction of light and heat in any substance," and he defines heat as a rapid motion of material particles. Athanasius Kircher, in his ponderous treatise, "*Ars Magna Lucis et Umbræ*," affirms that fire is air which is caused to glow by the violent collision of bodies, by which means combustible bodies become flame. At an early date it was observed that fire cannot exist without air; the experiment of burning a candle in a closed vessel was well known. Some affirmed that "air is the food of fire," some that "air nourishes fire." The influence of a blast of air upon fire was well recognised; we have seen that bellows were known at a very early date. When nitre—which for many centuries was one of the most important bodies in chemistry—came to be known, it was soon noticed that it produces intense ignition; that, in fact, to direct a blast of air upon a red-hot coal, or to throw some nitre upon it, produced the same result, viz. greatly augmented combustion. Hence arose the idea that nitre and the air are in some way connected, for "things which are equal to the same are equal to each other." This association of ideas may seem crude to us now, yet we must remember that nitre produces rapid combustion simply because it contains a great quantity of that constituent of the air, oxygen gas, which ordinarily produces combustion. Thus the old natural philosophers, wandering in the dim twilight of experimental knowledge, were not so far wrong in their supposition. The idea mentioned above was very prevalent two centuries ago: Robert Boyle speaks of the presence of a "volatile nitre" in the air; Lord Bacon says that nitre contains a "volatile, crude, and windy spirit"; Clark attributed thunder and lightning to the presence of nitre in the air; Gassendi imagined that minute particles of nitre are diffused throughout the atmosphere. When we heat lead or tin in a current of air, these metals are respectively converted into a powder, or *calx*, and calcination was one of the most important processes in old chemistry. Calcination seemed to be due more or less directly to the air; and metals could also be calcined by heating them with nitre, or with the spirit of nitre—nitric acid; hence arose another bond of connection between nitre and the air; at least, they had something in common. Lemery in his "Cour de Chimie," published in 1675, affirms that the acid of nitre contains a number of "*corpuscules ignées*" locked up in it, and he defines these latter as "a subtle matter, which having been thrown into a very rapid motion, still retains the power of moving with impetuosity, even when it is enclosed in grosser matter; and when it finds some bodies which by their texture or figure are apt to be put into motion, it drives them about so strongly that, their parts rubbing violently against each other, heat is thereby produced."

Thus recognising the causes which had led to the association of the air with nitre, at least so far as they are both concerned in the production of combustion, we are prepared to examine Robert Hooke's theory of combustion. The announcement of this theory marks an important history in the theory of chemistry; it was the first chemical theory worthy of the name, and it gave a far more just and accurate explanation of combustion than the crude and over-belauded theory of Phlogiston, of Becher and Stahl. Hooke's theory was, moreover, founded upon experiment, and although unfortunately he does not describe the experiments, we see at a glance that it could not have been constructed without such means. "This hypothesis," he writes, "I have endeavoured to raise from an infinity of observations and experiments," and all who know Hooke's writings, are well aware how good an experimenter he was. The theory was published in 1665 in Hooke's "*Micrographia*;" it is there found (Observation 16) buried in a mass of irrelevant matter, and to this cause may, perhaps, to some extent be attributed the fact that it has been so little recognised and known. The theory is stated in twelve propositions, the principal of which are as follows:—

1. That the air is the "universal dissolvent of all sulphureous bodies."

Sulphur was long regarded as the type of combustible bodies, on account of its ready inflammability; some even derive the name from *sal*, πῦρ, the salt of fire. By sulphureous bodies, Hooke simply meant combustible bodies, viz. bodies that can burn in a supporter of combustion. By air being the "universal dissolvent," he meant that through the agency of air combustible bodies are caused to become transformed into similarly invisible substances. For instance, we burn a pound of wood, and a few grains of ash remain, the rest has disappeared into air; as we say now, it has been converted into carbonic anhydride gas; as Hooke said then, it has been dissolved by the air.

2. "That this action it (the air) performs not until the body be sufficiently heated."

In more modern phraseology, every combustible possesses its special igniting point, phosphorus 92° F., sulphur 482° F., and so on.

3. "That this action of dissolution produces or generates a very great heat, and that which we call *Fire*."

4. "That this action is performed with so great a violence, and does so minutely act, and rapidly agitate the smallest parts of the combustible matter, that it produces in the diaphanous medium of the air the action, or pulse, of *Light*."

This would seem to indicate that Hooke considered light to be an intensified form of heat, and to be generated in the same manner, and to be a kind of very rapid motion.

5. "That the dissolution of sulphurous bodies is made by a substance inherent and mixed with the air, that is like, if not the very same with, that which is fixed in saltpetre."

Hooke had evidently traced the connection between certain actions produced by the air and by saltpetre or nitre; and he says it may be readily demonstrated that combustion is effected by that constituent of the air which is fixed in saltpetre. This is a remarkable assertion, because oxygen gas was not discovered until more than a century after the proposition of Hooke's theory; and we now know that nitre contains "fixed" in it the same substance—oxygen gas—which causes air to "dissolve" combustible bodies. It is probable that the connection between air and nitre may have been rendered the more probable in the minds of Hooke and his contemporaries by the knowledge that gunpowder will burn in a space devoid of air; thus, if sulphur and charcoal burn in air, and consume air in burning, and if nitre will cause them to burn out of contact with air it would surely appear that nitre must contain air, or one of its components.

10. "That the dissolving parts of the air are but few, ... whereas saltpetre is a menstruum, when melted and red hot, that abounds more with these dissolvent particles, and therefore as a small quantity of it will dissolve a great sulphureous body, so will the dissolution be very quick and violent."

It was well known that if a piece of red-hot charcoal be thrown into melted nitre, it is consumed with great rapidity, while in the air it burns with far less readiness; hence Hooke infers that that particular component of air which causes it to support combustion exists in a condensed form in saltpetre. He also remarks that if air be violently forced upon a piece of ignited charcoal by bellows it may be made to burn almost as rapidly as in melted nitre.

12. "It seems reasonable to think that there is no such thing as an *element of fire* . . . . but that that shining transient body called *flame* is nothing else but a mixture of air and volatile sulphureous parts of dissoluble or combustible bodies."

Hooke asserts that this theory had been worked out by him several years earlier, and had been well supported by experimental means; he says, moreover, that he has here "only time to hint an hypothesis, which, if God permit me life and opportunity, I may elsewhere prosecute, improve and publish" This he never did; but a young Oxford physician named John Mayow (b. 1645 d. 1679) eagerly accepted the theory, and adduced many experiments in support of it. Perhaps Mayow may have worked with Hooke, during his residence in Oxford, and may have helped to adduce verifications of the then half-formed theory. Mayow's experiments are contained in a treatise entitled—"*Tractatus Quinque Medico-Physici quorum primus*

FIG. 18.—John Mayow.
(From his "Tractatus Quinque Medico-Physici, 1674.")

agit de Sal-nitro et Spiritu Nitro-aëreo, Secundus de Respiratione . . . . Oxonii, 1674." The book is altogether important, because the experiments which it contains form the basis of pneumatic chemistry, that is the chemistry of gaseous bodies; it is also distinguished by accurate reasoning and well-founded generalisations. Had it been better known, it can scarcely be doubted that the discovery of oxygen and of various gases made a century ago, would have been forestalled by many years.

Mayow calls the "dissolving parts" of the air and of nitre, which we now call oxygen gas, by the several names of *nitre-air, fire-air*, and *nitro aërial spirit*. Air does not consist wholly of nitre-air, because when a candle is burnt in a closed vessel only a portion of the contained air is consumed Nitre-air exists in large quantities in a condensed form in nitre; hence combustible bodies mixed with nitre will burn under water, or in a vacuum. The acid of nitre contains all the nitre-air in nitre, but it does not inflame bodies so readily as nitre because in it the nitre-air is surrounded by particles of water which tend to quench the burning body. Nitre air is not combustible itself, neither does nitre contain any combustible substance, because it may be fused in a red-hot crucible, but no ignition will be observed to take place, until a combustible body has been added. All acids contain nitre-air:—how curiously this contrasts with Lavoisier's name *oxygen*, from ὀξυς γεννάω, which he gave to the gas, because he believed it to be an essential constituent of all acids. Sulphuric acid, according to Mayow, consists of nitre-air united with sulphur; wines become sour and are changed into vinegar by the absorption of nitre-air from the atmosphere. It is the cause also of fermentation and putrefaction, and for this reason, substances when covered with fat or oil do not putrefy. During calcination metals increase in weight, and this increase is attributed by Mayow to absorption of nitric air; thus calx of antimony is antimony *plus* nitre-air, and this is borne out by the fact that a substance absolutely similar to calx of antimony may be procured by treating the metal with the acid of nitre and evaporating Again, rust of iron is iron united with nitre-air.

We come now to some of the first experiments in Pneumatic Chemistry. In one of his experiments Mayow supported a kind of ledge within a bell-jar full of air (see Fig. 19); upon the ledge he placed a piece of camphor, and fired it by concentrating the rays of the sun by a lens upon it. The camphor ignited and burnt for some time, water then rose in the jar; and on again attempting to ignite the camphor he was unsuccessful. A lighted candle was also burned in the jar with the same result. Thus a part only of the air had been consumed, and the remainder was unable to support combustion. The siphon tube (shown on the right-hand side of the figure) was inserted at the commencement in order to render the height of the water the same, inside and outside the tube, as stoppered air jars were then unknown.

Thus it was clearly proved that air is diminished in bulk by combustion. In order to prove that respiration produces a

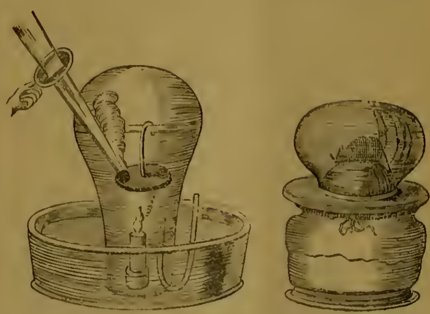

FIG. 19. FIG. 20.
Fig. 19.—Early experiment in pneumatic chemistry. Fig. 20.—Early experiment in physiological chemistry.

similar result, Mayow tied a piece of moist bladder over the mouth of a jar (Fig 20), and upon this he pressed a cupping-glass, so that the edges fitted air tight Within the cupping-glass he placed a mouse, and as the animal continued to breathe he noticed that the bladder was forced up, more and more into the cupping-glass, proving that the air within it had been diminished by the respiration. Thus Mayow endeavoured to establish a connection between combustion and respiration. He also placed a mouse in a vessel standing over water, and noticed that the water rose in the jar as the respiration continued; and he found it impossible to ignite a combustible body in a jar of air in which a mouse had died. Again, he placed a mouse and a lighted candle together in a jar of air, and he noticed that the mouse only lived half as long as a mouse lived in the same bulk of air without the candle. Air deprived of its nitre-air was assumed to be lighter than nitre-air, because if a mouse is placed near the top of a closed vessel, it dies sooner than if placed near the bottom.

In 1672 Robert Boyle procured hydrogen gas by acting upon iron filings with an acid, and proved its inflammability; but he does not appear to have further studied its properties, and its discovery is always attributed to Cavendish, a century later. Boyle suggests that it probably consists of "the volatile, sulphur of Mars, or of metalline steams participating in a sulphurous nature." Mayow also procured some of this gas by acting upon

iron with dilute sulphuric acid, and he proves that it is not a supporter of life.

Mayow's second treatise is on respiration, and he herein expresses views far in advance of any of his predecessors. He proved that the nitre-air is alone concerned in respiration, and he asserts that this is absorbed by the blood, while the rest is rejected. It unites with combustible particles in the lungs, and thus produces animal heat. The lungs consist of a number of minute sack shaped membranes through which the nitre-air passes to the blood.

We add the following *résumé* of Mayow's treatise, and of the position which it ought to occupy in the history of chemistry, from an article which we wrote on the subject a few years ago.

Mayow's work is remarkable in several respects. In it he conclusively proved that respiration and combustion are analogous processes; he upset the four-element theory by demonstrating the compound nature of air; and he recognised oxygen and nitrogen as clearly and almost as notably as they were recognised a hundred years later—the one the supporter of life and combustion, the principle of acidity, and the cause of fermentation and putrefaction, heavier than atmospheric air; the other incapable of supporting life or combustion, and lighter than atmospheric air. We find, moreover, in this work the dawn of the idea of chemical affinity in the *fermentation*, which he speaks of as taking place between nitre-air and combustible particles, and extending to the production or destruction of things. Mayow even employs some of the terms in general use in the present day; thus he speaks of *affinitas*, existing between acids, and earthy substances, and uses the words *combinetur* and *combinentur* in speaking of the *congressus* of different substances.

The treatise is characterised by much clear and condensed thought, well-sustained argument, and accurate reasoning; moreover, we seldom meet with instances of too hasty generalisation, always the dominant source of error in the early development of a science. We further observe a great advance towards that exact and discriminative mode of thought which is necessary for the investigation of chemical phenomena. The period in which Mayow wrote, was, as regards chemistry, a period of transition; there was as yet no work on scientific chemistry, yet Mayow's treatise approached more nearly to such a work than that of any of his predecessors. The works of previous writers in this direction belonged to one of the three following classes: they were either chemico-metallurgic, chemico-medical, or alchemical treatises, or they partook of the nature of all three. The publication of works on alchemy was fast waning before the advances of the new philosophy; for as superstition retreated, and as men began to devote their energies to the legitimate investigation of nature, a false and chimerical art must of necessity cease to find votaries. Mayow was the first to discuss the intimate nature of an intangible body; other writers had treated of the air as a whole, but no one had endeavoured to ascertain the nature of its internal constitution, or to determine why it produces certain changes in surrounding bodies, upon what these changes depend, and the nature of the constituent or constituents of the air producing them. The old dogma of the elemental nature of the air was received as an absolute truth, although entirely unproven; it was thought that a theory which had been received since the earliest ages must of necessity be correct, and no attempt was made to disprove it.

We see from the above that it was the investigation of the nature of nitre which led to the knowledge of the constitution of the air, and to the first experiments in pneumatic chemistry. Mayow remarks at the commencement of his treatise, that so much had been written about nitre, that it would appear "*ut sal hoc admirabile non minus in philosophia, quam bello strepitus ederet; omniaque sonitu suo impleret;*" and when he remembers its connection with the foregoing results we are almost inclined to agree with him.

G. F. RODWELL

SCIENTIFIC SERIALS

THE *Journal of Botany* for April commences with two useful papers on Cornish botany: Supplementary Contributions to the Flora of North Cornwall, a very little known district, by Mr. J. G. Baker, and another by Mr. T. Archer Briggs.—Mr. F. E. Kitchener contributes a very interesting note on Cross-fertilisation, as aided by sensitive motion, in Musk and Achimenes, the former from observations of his own, the latter from those of Miss Dowson. The structure and motion of the sexual organs, which have long been known in both these flowers, are clearly shown to be contrivances for ensuring cross-fertilisation by insect-agency.—Dr. M'Nab, in a short paper, suggests the employment of the term "pseudocarp," to distinguish fruit-like structures from true fruits, such, for instance, as the apple, the strawberry, the rose-hip, the mulberry, and the fig, into the composition of which other organs besides the true fruit enter. Among the short notes, the most interesting is one of the discovery of *Echium plantagineum* in Cornwall, by M. Ralfs, the plant having been hitherto confined, as far as British botany is concerned, to the Channel Islands. There is a coloured illustration of four new Hymenomycetous fungi, by Mr. W. G. Smith.

Poggendorff's Annalen, No. 1, 1873.—This number opens with the fourth of a series of papers, by Oscar Emil Meyer, on the internal friction of gases; he shows that Poiseuille's law for droppable fluids is verified for gaseous transpiration through narrow pipes.—Dr. Hermann Herwig communicates an account of experiments made on the action of the induction spark in explosion of gaseous mixtures; this action varying with pressure and concentration in the mixture, and with the quantity of electricity passed.—An apparatus of physiological interest, termed the Physometer, is described by P. Hartwig. It is a refinement on Robert Boyle's idea for examining the action of the swimming bladder in fish. The fish, enclosed in a wire cage, is elevated or depressed at will in a vessel filled with water, while the changes of volume in the animal are indicated by the rise and fall of water in a thin tube connected with the vessel.—Dr. Pfeffer, in a paper on the decomposition of carbonic acid in plants by the different spectral rays, infers from his experiments that the curve representing the decomposition mainly corresponds with the curve of brightness.—This paper is followed by another on a similar subject, by E. Gerland. Among the remaining articles may be noted those on the Synaphy (or cohesion) of ethers, by Dr. Scholz, on the polarisation and colour of light reflected in the atmosphere, by E. Hagenbach, and on the electromotive force of very thin gaseous layers on metallic plates, by F. Kohlrausch.

No. 2 contains one of a series of papers, by Julius Thomsen, entitled *Thermo-chemische Untersuchungen*. In the present number he investigates the affinity of hydrogen to the metalloids, chlorine, bromine, and iodine.—Oscar Meyer also continues his series on internal friction of gases; giving a detailed account of two kinds of apparatus for estimating the influence of temperature on friction, and adding some valuable observations on the dynamical theory of gases.—Several new apparatuses are described in this number, Prof. Mayer, of Hoboken, explaining a method of observing the phases and wave-lengths of sound-vibrations in air, and also his acoustic pyrometer based on this method; while an improved deep-sea thermometer, a new form of siphon, and a photometer based on the perception of relief, are described by their several inventors.—A second paper on the physometer is also communicated by P. Hartwig, in which the physiological and other applications of the instrument are more fully discussed.—W. Feddersen contributes an account of a phenomenon which he proposes to call *thermo-diffusion*, and which occurs when two portions of gas are separated by a porous diaphragm, the opposite sides of which have different temperatures. A diffusion is observed which, unlike the ordinary diffusion, takes place when, on both sides of the diaphragm, there is the same gas with the same pressure.—Dr. Morton communicates a note on fluorescence, supplementary to Hagenbach's researches; and there are, in addition, a few notes from English and other sources.

Revue des Sciences Naturelles, Nos. 1-3, 1872.—This new quarterly journal, published at Montpellier, is another proof of the scientific activity which is now reviving in France. Like Lacaze Duthier's *Archives de Zoologie*, this provincial review will we trust exhibit what Prof. Jourdain calls in one of these numbers "ces qualités éminemment françaises : la méthode, la rigueur et la clarté," combined with *Deutscher Fleiss una Unbefangenheit*, which though of late years less common in France may well be reclaimed as no alien virtues by the countrymen of Descartes, and Cuvier, and Laennec. The editor is M. Dubrueil, with whom Dr. Heckel was associated in the first two numbers. Among the contributors are the names of Andouard, Barthélemy, Boyer, Paul Gervais, Joly, Jourdain, Robin, Malinowsky. The first number opens with a paper by Prof. Joly, on the development of the Axolotl, illustrated with some good drawings. There follows a short communication on a new French mollusk (*Pisidia Dubrueui*), an introductory lecture on botany, and an account of the geology of

the neighbourhood of Montpellier. Perhaps the most important part of this and the subsequent numbers is a series of careful abstracts of French and foreign publications in zoology, botany and geology. The second number contains a botanical paper on certain Juncaceæ, by Duval-Jouve, with plates; a new classification of Mammalia, by Prof. Contejean (there is nothing very new in it: the chief novelties are definitely uniting the elephant with Rodentia, and separating the Pinnipedia from the other Carnivora to associate them with Sirenia and Cetacea); a description of diatoms found in the mixture of various corallines and algæ which is known in pharmacy as "Mousse de Corse" (*Corallina corsica*, "sea-moss"), by A. de Brébisson; and a short account with a plate of the remarkable Filaria discovered in chylous urine, by Wucherer and T. R. Lewis, and lately found in human blood by the latter observer. Among the abstracts of this number, by Prof. Jourdain, is an interesting review of the affinities of *Amphioxus* and the Tunicata from an anti-Kowelevskian point of view, by Prof. Jourdain, *àpropos* of Giard's *Etude* on the subject in the *Archives de Zoologie.* The third number, published last December, contains, among other articles, an important communication from M. Bavay on the development of a frog (*Hylodes Martinicensis*, Tschudi), observed in the island of Guadaloupe. Though it issues from the egg as a perfect anurous abranchiate Batrachian, it can be seen in the semi-transparent fœtal coverings to go through the tadpole stage, having a well-developed tail and small external gills, both of course functionless. We congratulate M. Dubreuil on his enterprise and success, and hope he will be able to maintain the high character of the first three numbers of his review. P. S.

SOCIETIES AND ACADEMIES

London

Chemical Society, April 17.—Dr. Odling, F.R.S., president, in the chair.—Dr. Debus, F.R.S., delivered a lecture "On the Heat produced by Chemical Action." The speaker considered the relation existing between the chemical affinity of the metals and the amount of heat they develop during oxidation or combination with chlorine, iodine, &c., and also the various interesting conclusions which may be drawn from the thermic results obtained by the solution of salts, especially noticing that, in double decomposition taking place in solution, those compounds are always produced which develop the greatest amount of heat.

Geologists' Association.—Excursion to Banbury, April 14 and 15.—This, the first excursion of the season, was under the direction of Prof. Morris and Mr. T. Beesley, and was largely attended. After their arrival at Banbury, the members and their friends examined exposures of the Middle Lias Clays (zone of *A. capricornus*) and the marlstone in the immediate vicinity of the town. Subsequently the party proceeded southwards, visiting at Twyford a section of the Lower Middle Lias, and at King's Sutton an extensive exposure of the marlstone which is here worked for ironstone. Fossils, especially Brachiopoda, are numerous at this place, and abundant occupation was found for the hammers of the party. At Newbottle Prof. Morris described the physical geology of the district, and showed how the hills and valleys, the agriculture, the occupations of the people, and even the houses and churches of a district, depended upon its geological structure. In the evening the members were entertained at a conversazione in the Town Hall, Banbury. A very fine collection of the local fossils as well as of antiquities and other objects of interest, had been brought together by the exertions of Mr. Beesley, and a large assembly testified to the interest the visit of the Association had occasioned. During the evening Prof. Morris delivered a lecture in which he described generally the geology of Banbury, and enlarged upon the advantages of a study of the science. The route for the second day was a long one, and the party left Banbury early, and proceeded by Constitution Hill section of Upper Lias, Broughton Castle and Church, Tadmarton quarries of great oolite, and Camp, Bloxham Church, Comb Hill quarry in inferior oolite, and Adderbury ironstone quarries in marlstone and upper lias. The physical and stratigraphical geology was explained at the various stopping places, and many fossils were obtained at some of the sections. At Tadmarton Mr. Beesley had provided luncheon for the members and visitors, who, while assembled in an ancient British camp, were addressed by Prof. Morris, Mr Beesley, and Mr. Lobley. The association has, during the present session, paid visits of inspection to the British Museum, the Museum of the Royal College of Surgeons, and the Museum of Practical Geology, and lectures descriptive of portions of the collections have been delivered by W. Carruthers, F.R.S., Prof. Morris, F.G.S., Prof. Flower, F.R.S., and R. Etheridge, F.R.S.

Dublin

Royal Irish Academy, April 14.—Dr. Stokes, F.R.S., vice-president, in the chair.—Professor R. Ball, LL.D., read some Notes on Applied Mechanics, and the secretary read, for Mr. Donovan, a description of a Comparable Self-registering Hygrometer.

Riga

Naturforscher Verein, Aug. 28, 1872.—Cand. Westermann described his visit to the Ilsingsee, in which is an island that periodically appears and disappears. It generally makes its appearance above water as the warm weather comes on, and the phenomenon is supposed to depend on the development in the peat at the bottom of marsh and coal gas, which is increased by the heat, and causes the masses of peat to float upwards towards the surface.

September 25.—Herr C. Berg gave a detailed report of Dr. Müller's work on the "Application of the Darwinian Theory to Flowers and Flower-frequenting Insects."

October 2.—Dr. Kersting exhibited some living young frogs, which had been from four to six weeks in the tadpole state. While some had already completed their development, others were still at various stages of transformation; one animal had all four legs, but still retained its long tail, while another was as yet only a biped. In proportion as the feet developed, the animal became all the more meagre, and at the same time the taste. the tail disappeared.—Herr Thoms produced some pieces of the so-called sugar boxwood, an inferior kind of South American mahogany, in which a remarkable secretion of a white hard substance had been found. He found it of the following composition:—Ca O 33·24. PO_5 42·30. Organic matter 3·06. Water 21·40, which is expressed in the formula $2\ Ca\ O + PO_5 + 4\ HO$. This is almost the same composition as that of the substance which gathers round the kidneys of the sturgeon.

October 16.—Prof. Kieseritzky gave a list of plants rarely met with in the province around Riga.—Dr. Bienert read a paper on the *Coniferæ*.

Vienna

Geological Institute, March 5.—Dr. R. v. Drasche showed a mineral that was found in the environs of Plaben, near Budweis, in South Bohemia. The specimens show a white nucleus which consists of felspar, and contains in almost equal proportions lime, potass, and soda. This nucleus is surrounded by a perfectly homogeneous, pellucid green mineral, which sometimes enters in small veins into the felspathic substance; the microscopic examination of this green mineral shows not only the polyhedric forms of the metamorphosed feldspar, but even the stripes characterising the feldspar-twins (*Zwillings-streifung*) are clearly visible. There can be no doubt therefore that the green mineral is a real pseudo-morphosis of feldspar; it belongs to the family of the chlorites and in its properties and chemical constitution is most similar to the pennine or to the pseudophite, described by Kenngott from Mount Idiar in Moravia.—T. Posepny on tube-ores (*Kohren Erze*) from Raibl in Corinthia. In the lead mines of Laibl there are to be found stalks, some lines in diameter and some inches in length, consisting in the outer part out of crystalline galena, whilst the axis is either quite hollow, or is filled with earthy matter. These tubes are inclosed in the dolomite which is the bearer of the lead ores of the country. M. Posepny thinks that these tubes are formed by the deposit of the galena on real stalactites.—M. Ch. v. Hauer on the occurrence of different sorts of coal in one and the same bed. By an accurate investigation of the brown coal of different localities in Styria, the author stated that it consists generally of two different sorts of coal which are mechanically mixed in the same bed, and sometimes in every single specimen. The one sort shows a rather slaty fracture, is faint, compact, and of less heating power; the other, on the contrary, has a conchoidal fracture, is shining, more easily friable, of greater heating power, and may be coked. In the same way in some layers of lignite v. Hauer found small parties of shining coal which resembles good brown coal; he is inclined to suppose that such differences of the coal in the same bed may

be caused by differences of the vegetables out of which the coal has been formed.

PHILADELPHIA

Academy of Natural Sciences, Oct. 1, 1872.—Prof. Leidy remarked that he had visited a corundum mine recently opened in the city of Unionville, Chester Co., Pa. The accumulation is perhaps the most extraordinary discovered, and its extent yet remains unknown. The corundum, as exposed to view at the bottom of a trench, appears as the crest of a large body or vein lying between a decomposing gneiss and a white talcose schist. The exposed portion averages about six feet in depth and five feet in thickness at bottom, and is estimated to contain about fifty tons. It looks as if it promised to be the most valuable deposit of corundum ever found. The corundum is the pure material, and is not emery.

October 8.—Mr. Thomas Meehan remarked, that as botanists well knew, *Quercus prinoides* seldom grew more than two feet in height. It was one of the smallest of shrubs. In his collections in Kansas, he found oaks in the vicinity of Leavenworth, which made small trees from ten to fifteen feet high, and with stems from one to two feet in circumference. He was entirely satisfied that it is identical in every respect but size with the *Q. prinoides* of the Eastern States. Among trees there are few which produce forms as low shrubs; but the *Pinus Banksiana*, in the East but a bush of five or ten feet, grew often forty feet along the shores of Lake Superior; the *Castanea pumila*, Chinquapin chestnut, when it gets out of the sands of New Jersey into the clayey soils west of the Delaware, often grew as large as many full-grown apple trees; while the *Celtis occidentalis*, which in the East is generally but a straggling bush along fence corners, is in Ohio a large spreading tree with enormous trunk, and in Indiana is as lofty and as graceful as an elm.

PARIS

Academy of Sciences, April 7.—M. Bertrand in the chair. The following papers were read:—On batteries and on electro-capillary actions, by M. Becquerel.—On a new method for the application of the third theorem to the control of geodetic lines and to the determination of the true figure of the earth, by M. Yvon Villarceau.—On the discovery of Lunar variation by Aboul Wefâ, by M. Chasles.—On an accessory reduction in the number of periods produced by juxtaposition at the moment of the formation of a double point, by M. Max Marie.—On Metallic Reflection, by M. Mascart.—On the action of electric currents on atmospheric air, by M. Boillot; a paper dealing with the formation of ozone by tubes coated with carbon powder.—Note on a new series of samples of crystalline or crystallised substances obtained in the dry way, by M. Ch. Feil.—A letter was received from M. Van der Mensbrugghe, stating that he had been completely convinced by the arguments and experiments of M. Gernez and Violette, in the recent controversy on crystallisation, and seeing that the superficial tension of liquids did not play the important part he assigned to it, he requested the Academy to consider his recent papers as not received.—A note on Tempel's comet (1867, II), was received from M. Stephan.—On composite electric sparks, by M Gazin.—On the Phonoptometer, an instrument for the study of periodic or continued movement, by M. J. Lissajous.—Note on the effects produced by currents of electricity on mercury immersed in different solutions, by M. Th. du Moncel.—On the solvent action of glycerine on metallic oleates, calcic oleates, and calcic sulphate, by M. Asselin—On the action of chloracetylic chloride on aniline and toluidine, by M D. Tommasi.—On the toxic effects of the iodides tetramethylammonium, and tetramylammonium, by M. Rabuteau; the author has found that so long as an atom of hydrogen remains unreplaced, the amyl and methylammonium compounds are harmless, but that as soon as the last atom of hydrogen is replaced by the radicle, the body becomes excessively poisonous, with an action like that of curara.—On the age of elevation of Mount Lozère, by M. Fabre.—Note on the public fountains of Toulouse, by M. Grimaud de Caux. During the meeting an election to the vacant chair of the late M. Delaunay, in the astronomical section, took place. M. Loewy obtained 31, M. Wolf 24, and M. Stephan 2 votes; M. Loewy was declared elected.

April 14.—M. de Quatrefages, president, in the chair.—Explanation of the text of Aboul Wefâ on the third irregularity of the moon, by M. Chasles.—A long and detailed reply to M. Faye's late criticism on the solar spot theory was received from Father Secchi; this was followed by an answer by M Faye, who also answered M. Vicaire's attempted revival of Herschel's theory in the same paper.—A correspondent for the astronomical section, in place of the late M. Quoy, was then elected, M. Mulsant obtained 31 votes, M. Baudelot 8, and M. Joly 1; M. Mulsant was therefore declared duly elected.—A report on M. Boussinesq's "Essay on the theory of running waters" was then read.—On the residues relative to Asymptotes, classification of the quadratics of algebraic curves, by M. Max Marie.—New observations on the theory of solar cyclones, by M. Vicaire.—A memoir on substitutions (mathematical), by M. C. Jordan.—On a new determination of the constant of attraction and of the mean density of the earth, by MM. A. Cornu and J. Baille.—On the effects produced by electric currents on mercury immersed in different solution, by M. Th. du Moncel, a continuation of the paper read at the last meeting.—On irradiation, by M. F. P. Le Roux.—On the hybrid reproduction of Echinoderms, by M. A. F. Marion. -On the trunk of a Nemertian hermaphrodite from the coasts of Marseilles, by M. E. Zeller.—A study on the carboniferous formations of the Bas Boulonuais, by MM. Gosselet and Bertaut.

DIARY

THURSDAY, APRIL 24.

ROYAL SOCIETY, at 8.30.—On the Durability and Preservation of Iron Ships, and on Rivetted Joints Sir W. Fairbairn.—On the Employment of Meteorological Statistics in determining the best course for a Ship whose Sailing Qualities are known: F. Galton.
ROYAL INSTITUTION, at 3.—Light: Prof. Tyndall.
GRESHAM LECTURES, at 7.—On Climate: E. S. Thompson.

FRIDAY, APRIL 25.

ROYAL INSTITUTION, at 9—Palæontological Evidence of Modification of Animal Forms: Prof. Flower.
HORTICULTURAL SOCIETY, at 3—Lecture.
QUEKETT CLUB, at 8.
GRESHAM LECTURES, at 7.—On Climate in Health and Disease: E. S. Thompson.

SATURDAY, APRIL 26.

GRESHAM LECTURES, at 7.—On Stimulants: E. S. Thompson.
ROYAL INSTITUTION, at 3.—Ozone: Prof Odling.
ROYAL BOTANIC SOCIETY, at 3 45.
GEOLOGISTS' ASSOCIATION, at 8—Excursion from Charing Cross (2.25) to Charlton.

MONDAY, APRIL 28.

GEOGRAPHICAL SOCIETY, at 8 30.—On the probable existence of unknown Lands within the Arctic Circle: Capt. Sherard Osborn, R N.
LONDON INSTITUTION, at 4.—Elementary Botany: Prof. Bentley.

TUESDAY, APRIL 29.

ZOOLOGICAL SOCIETY, at 8.30.—Anniversary.
ROYAL INSTITUTION, at 3 Music of the Drama: Mr. Dannreuther.
SOCIETY OF ARTS, at 8.—On the British Settlements in West Africa: Governor Pope Hennessy.

WEDNESDAY, APRIL 30.

LONDON INSTITUTION, at 12.—Annual Meeting.
SOCIETY OF ARTS, at 8.—On the Condensed Milk Manufacture: L. P. Merriam.
GEOLOGICAL SOCIETY, at 8.—On the Permian Breccias and Boulder-beds of Armagh: Prof. Edward Hull—Geological Notes upon Griqualand West: G W Stow.—On some Bivalve Entomostraca chiefly Cypridinidæ, of the Carboniferous Formations: Prof. T. Rupert Jones.

THURSDAY, MAY 1.

LINNEAN SOCIETY, at 8.—On Cinchonas: J. E. Howard.
CHEMICAL SOCIETY, at 8.—On Zirconia: J. B. Hannay.—On a new class of Explosives: Dr. Sprengel.
ROYAL INSTITUTION, at 2.—Annual Meeting.

THE WILD BIRDS PROTECTION ACT

"SAVE me from my foolish friends," ought to be a stave in the spring-song of each fowl of the air, from the Nightingale which warbleth in darkness to the Dotterel which basketh at noonday. Last year, as is well known, a bill for the protection of "Wild Fowl" was brought into Parliament at the instance of the "Close-time" Committee of the British Association,* and the various changes and chances which befell it before it became an Act were succinctly recounted in the Committee's report at the Brighton meeting, printed in NATURE, vol. vi. p. 363.

This bill, as at first prepared and introduced to the House of Commons, was framed entirely on the Sea-birds Preservation Act, which became law in 1869, and only differed from that successful measure where difference was needed, and the penalties and procedure it proposed were the same as those which have proved to be so thoroughly efficient in the former case. The minute care, the practical knowledge, and the consideration of various interests with which it was originally drawn, may be gathered from a few facts. Many of the birds it intended to protect are known in various parts of the country by various names, and accordingly all these names were introduced, for it was clear to the promoters of the bill, though not, as shown by the sequel, to the public at large, that a man summoned for killing (let us say) a Lapwing would never be convicted if he brought, as he easily might bring, credible witnesses who in good faith swore that it was a Peewit, and that they never heard it called anything else. At the same time, that the measure might not be needlessly severe, care was taken that of those species which bear different names in Scotland and England and do not breed in the latter, they should only appear under the name by which they are known in the former. A few species too, though coming strictly under the category of "Wild Fowl," were omitted because of their making themselves obnoxious to farmers. But the great feature of the bill was its being directed to a definite point—the preservation during the breeding season of those birds which, beyond all others, were and are subjected to cruel persecution at that time of year—thousands of Wild Ducks, Plovers, and Snipes, being constantly to be found in the poulterers' shops throughout the spring months, not only killed while they are breeding, but killed, it is not too much to say, because they are breeding, since during that season they put off much of their natural shyness and fall easy victims to the professional gunners. Furthermore, all who really know anything of birds know that it is just these kinds which are most rapidly diminishing in number—some of them, which in bygone days were most abundant, are now only seen as stray visitors. There is, for example, the Avocet, the disappearance of which can be plainly traced to its destruction by gunners,* and had we space we could cite many similar cases. Then too, nearly all these birds are of no small importance as an article of food, and their supply to our markets has produced a trade of considerable extent.

Now, on the other hand, there are a good many enthusiastic persons, of whom we desire to speak with all respect, who have long been under the belief that in this country the number of birds generally, and of small birds in particular, has been gradually diminishing, and these persons wished for a much wider extension of the principle of protection than seemed to the "Close-time" Committee necessary or expedient. Whether their zeal is according to knowledge may be judged from what we have further to relate, but it is very plain that they disregard the widespread belief in the mischief popularly supposed to be caused by many of even our most useful small birds, and the fact, which no observer of experience can deny, that under certain circumstances, certain birds do a very considerable amount of harm—witness Song-thrushes and Blackbirds in the strawberry-beds—as well as that it is

* This Committee in 1871-72 consisted of Mr. Barnes, one of the secretaries of the Association for the Protection of Sea-birds, Mr. Dresser (reporter), Mr. Harting, Prof. Newton, and Canon Tristram, and it may be doubted whether five gentlemen more thoroughly conversant with the subject could have been selected. Mr. Harland, the other secretary of the Sea-birds' Association, has since been added to their number.

* See Stevenson's "Birds of Norfolk," vol ii. p. 237 and following pages.

only careful observation which will convince an unprejudiced man that the harm so done is outweighed by the general good. Further, too, these persons overlook the impossibility of making people change their opinions by Act of Parliament, and it could be only when they become better acquainted with the great truths of natural history, that the desired results would follow. An attempt to force public opinion in this country generally fails.

Now this being the state of things when the "Wild Fowl Protection Bill" was introduced by Mr. Johnston, the enthusiasts at once tried to make it meet their ends. The history of the bill being, as we have said, accessible to our readers, there is no need for us to enter upon details, and we content ourselves by reminding them that, in an almost deserted House, Mr. Auberon Herbert, on the motion for going into committee, succeeded in carrying, by a majority of 20 to 15, an "instruction" to extend the protection accorded under the bill to "Wild Fowl" to other wild birds, and thereupon the spirit of the Bill was entirely changed, and it was converted from the reasonable measure originally contemplated into one of indefinite and general scope. Persons of common sense at once saw that in its new shape it would be impracticable, not to say tyrannical, and notice was speedily given of its rejection. Its introducer, however, contrived to get it referred to a Select Committee, by whom it was still further modified, the objections naturally urged against its sweeping clauses being overcome by limiting its effects to certain birds named in a schedule, while the penalties were diminished. The schedule, it is true, contained the names of all those birds originally included in the Bill, but m ny others were added, though on what principle some were omitted and others introduced we cannot profess to say. No ornithologist whose opinion could carry the slightest weight appears to have been consulted, and it is needless to say that no ornithologist was among the twenty-three members forming the Select Committee.*

We need not dwell further on historic details. It is now evident that the efforts of the enthusiasts—well intended as they doubtless were—have produced a law which is on all sides admitted to be virtually inoperative, instead of the effective measure which the results of the Sea-birds Act warrant us in believing that the original Bill would have proved. Substantial fines, which would have been resonable enough where professional gunners and poulterers were concerned, would have been manifestly cruel in the case of schoolboys. Accordingly the penalties were, to use the forcible expression we have heard applied, "sweated away" to suit the minor offenders, and the Act is almost a dead letter. Mr. Herbert, on the 21st of June last, laid a cuckoo's egg in the carefully-built nest of the British Association Committee, and the produce is a useless monster—the wonder alike of the learned and the layman, and an awful warning as an example of amateur legislation. The forebodings of the "Close-Time" Committee have proved but too true. In its last Report we read—

"Your Committee cannot look with unmixed favour on this measure. It appears to them to attempt to do too much, and not to provide effectual means of doing it. In their former Reports they have hinted at, if not expressed, the difficulty or impossibility of passing any general measure, which, without being oppressive to any class of persons, should be adequate to the purpose. Further consideration has strengthened their opinion on this point. They fear the new Act, though far from a general measure, will be a very inefficient check to the destruction of those birds, which, from their yearly decreasing numbers, most require protection, its restraining power having been weakened for the sake of protecting a number of birds which do not require protection at all. Your Committee have never succeeded in obtaining any satisfactory evidence, much less any convincing proof, that the numbers of small birds are generally decreasing in this country; on the contrary they believe that from various causes many, if not most, species of small birds are actually on the increase. They are therefore of opinion that an Act of Parliament proposing to promote their preservation is a piece of mistaken legislation, and is mischievous in its effect, since it diverts public attention from those species which, through neglect, indifference, custom, cupidity or prejudice, are suffering a persecution that will, in a few years, ensure their complete extermination."

We believe that this opinion is entirely correct, but our space would not allow us to adduce evidence in support of it. Mr. Herbert has now confessed the inutility of his handy-work, and some time since gave notice of a motion for the appointment of a Committee of the House of Commons to examine witnesses on the question. Before this article appears in print, our readers will know whether he gets what he wants. If he succeeds we suspect that not much good will follow. The eloquence of the enthusiasts is likely to overpower the reason of the true naturalists—a race not prone to sentimentality or given to sensationalism.

We would observe that the destruction of "Wild Fowl" stands on a very different footing from the destruction of "Small Birds," and if either is to be stopped it must be by different means. To check the first we believe no measure can be devised so complete as that which was last year spoilt by Mr. Herbert, but, since his unhappy success has taught Leadenhall Market that an Act of Parliament may be set at nought with impunity, it is quite possible that a new Act to be effectual should absolutely prohibit, within certain days, the possession or sale of the birds to be protected, irrespective of whether they can be proved to have been received from abroad or not. The destruction of "small birds" is chiefly caused by professional bird-catchers, for the numbers killed by the gun is in most cases comparatively trifling. The outcry that would be raised by farmers and market-gardeners, were they hindered from shooting the birds they find rifling their crops, would quickly repeal any Act which Parliament might inconsiderately pass to that effect. But we certainly should have no objection to putting the bird-catchers under some restriction, and we believe it would be to their own advantage if they were restrained from plying their art during the breeding-season. We shall no doubt be condemned by many excellent persons, but we cannot look upon bird-catchers as a class that should not be suffered to exist. The vocation of a bird-catcher may or may not conduce to the practice of all the virtues, but there is no reason for regarding it as essentially and necessarily vicious. Good and bad exist in every trade, bird-catching among the rest. We conceive that Mr. Sweedlepipes had a right to

* The printed "Proceedings" of the Select Committee do not throw much light on the subject The schedule was proposed by Mr Samuelson On a division the Owl was saved by 14 votes to 4, the Hedge-Sparrow and Whinchat by the casting vote of the chairman, the Thrush was lost by 9 to 6. All the birds added are included only under their book-names, which of course are, as every practical naturalist is aware, very different from those by which they are commonly known.

make his living—nay, to be protected in doing so as long as he did not exercise his calling to the detriment of the community. Of course this view will not suit the spasmodic writers of letters to the *Times* and other newspapers with their passionate appeals on behalf of the harmless Hedge-Sparrow and the unappreciated Tomtit. Who is there that systematically persecutes either? Certainly not the bird-catcher even of the blackest dye, begrimed with the soot of Seven Dials or Spitalfields. Are there not just as many Hedge-Sparrows and Tomtits in this country as there is room or food for? Are there not now many more Skylarks and Chaffinches than there were before heaths were broken up and bogs drained, plantations made and "vermin" killed by the gamekeepers? But our excellent enthusiasts cannot see this: with them are alike despicable and detestable the gardener who will not believe that the Bullfinch is actuated by the purest and most benevolent motives in nipping off his apple-buds, and the farmer who doubts whether the Sparrow's ravages in his ripening grain are counterbalanced by that saucy bird's services in the cabbage-garden. To them all birds are at all times bent on benefiting the human race. No statement in this direction is too gross for such people to swallow. The last we have met with is one of the most absurd. In the *Quarterly Review* for the present month (p. 402), we read that from some nameless moors the sportsman has been driven by the vipers, and the abundance of the vipers is owing to the extermination of "their natural enemy, the beautiful peregrine falcon"! Such a story is not worth refutation; its original teller has said "that which is not," and the man who gravely repeats it is an idiot or worse.*

But now to conclude, we beg leave to offer the following suggestions:—

1st. That the "Wild Fowl Protection Bill" be passed as originally introduced, with the possible exception of the sentence whereby fowls proved to have been imported from any foreign country are exempted.

2nd. That a "Bill for the Regulation of Bird-catchers" be brought in—its chief feature being the absolute prohibition of bird-catching by means of traps, springes, or nets during the spring months—say from April 1 to July 1, and that at other times of the year such engines should not be used within (say) 50 yards of any highway.

3rd. That the "sport" of Swallow-shooting be absolutely and at all times prohibited; and finally we may add that if a Chancellor of the Exchequer should ever take a hint from North Germany and lay a tax on birds in cages, we in the name of our Nightingales shall thank him.

* It is painful, however, that such folly should be countenanced by reviews which in other respects are deserved y of high repute. But in no department of criticism is there such a want of competent writers as in Zoology. We are not exaggerating when we say that nine out of ten reviews of zoological works are written by men who have no sound knowledge of the elements of the science.

FAUNA DER KIELER BUCHT

Fauna der Kieler Bucht. Zweiter Band: *Prosobranchia und Lamellibranchia, nebst einem supplement zu den Opisthobranchia.* Mit 24 tafeln. Von H. A. Meyer und K. Möbius. Small folio, 139 pp. (Leipsic, 1872.)

WE are rejoiced to see the second volume of this excellent "*ouvrage de luxe*." Like the first volume, the second bears evident marks of having been prepared with the greatest care. The illustrations are inimitable and life-like: we venture to say that no such figures of Mollusca and their shells have ever been published in any country.

The introduction to the present volume contains an account of the currents, saline ingredients, and temperature of the water in Kiel Bay, together with elaborate tables of the latter properties in comparison with those in some other parts of the North Atlantic and in North Japan, as well as a notice of the peculiarities, distribution, and frequency of occurrence of the Kiel Bay Mollusca, and relative abundance of the genera and species in proportion to that of the Mollusca in Great Britain, Christianiafiord, and the Sound.

The body of the work embraces the subclass Prosobranchia (comprising the orders Cyclobranchiata, Pectinibranchiata, and Siphonobranchiata) of the class Gastropoda, a supplement to the first volume in respect of the other sub-class Opisthobranchiata (orders Pleurobranchiata and Pellibranchiata), and the Lamellibranchia (order Lamellibranchiata of the class Conchifera), with short diagnoses in Latin, and full descriptions in German of all the species given in the work. The admirable figures amply illustrate every character of the living animal and its shell, some being of the natural size, and others magnified 300 times.

We are not told whether any Brachiopod, marine Pulmonobranch, or Cephalopod inhabits Kiel Bay; but assuming the list to be complete, we find 23 species of Conchifera, and 40 of Gastropoda, being altogether 63 species. There are 562 species of Mollusca in the British seas. This great difference may arise from the brackish nature of the water in Kiel Bay; and to the same cause may be attributable the small size of all the Mollusca, except *Mytilus edulis*, which is usually stunted on the open sea coast.

The authors have satisfactorily shown that the genus *Triforis* (erroneously changed by Deshayes to *Triphoris*) is distinct from *Cerithium*, although belonging to the same family, between which and *Cerithiopsidæ* it appears to be intermediate. The principal difference consists in the animal of *Triforis* having a retractile proboscis; and Lovén's description of *T. perversa* was doubtful on that point. Other writers on the Mollusca have done nothing to help us in the classification of this difficult group. The shells are distinguishable by the shape of the mouth, which is very peculiar in *Triforis*; and the sculpture of the apex differs from that of *Cerithium*—an important character which might have been advantageously represented in the plate before us.

We hope the authors will not take amiss a few slight criticisms. Their *Rissoa inconspicua* is not Alder's species, but *R. albella* of Lovén. *R. octona* of Linné is probably a variety of *Hydrobia ulvæ*, judging from his description and the habitat "in Sveciæ subpaludosis." The species described and figured by Meyer and Möbius as *R. octona* has two more (viz. ten) whorls; it is not horn-colour, but variegated; the mouth is oval, and not "fere orbiculata;" and Linné does not mention the ribs which characterise the Kiel Bay species. The figures of *Rissoa striata* do not show the foot-appendage or caudal cirrus, although it is described in the work. *Amphisphyra* should be *Utriculus*.

We wish the authors could have given us some information as to the *modus operandi* of the *Teredo* in excavating its cylindrical tube, instead of merely quoting Kater's opinion that the shell is the boring organ. One thing is certain, and indeed has been admitted by Kater, that the foot of *Teredo* is in front, occupying the bottom of the tube, while the shell at the same time occupies that part of the tube which lies immediately above the foot, and is closely pressed against the sides of the tube. To suppose that the position of the foot and shell could be reversed by the animal, so as to make the shell lie at the bottom of the tube and the foot on one side during the process of excavation, is quite inconsistent with our knowledge of the *Teredo* and of the babits of other boring and burrowing Mollusca. *Solen*, *Cardium*, *Natica*, *Actæon*, and many other kinds burrow in sand by means of their strong muscular foot; *Pholas dactylus* occasionally does the same; and the limpet uses its foot only for excavating the hard rock in which it is sometimes more or less deeply imbedded. The gradual enlargement throughout of the tube of *Teredo*, especially at the opening (where the siphons are placed), cannot possibly be caused by the shell, which invariably lies at the other end: and the prickles which cover the surface of the shell, and enable it to act as a fulcrum or *point d'appui*, could not be renewed if they were continually employed in rubbing away the wood. There can scarcely be a question that the foot is the sole instrument of perforation in *Teredo*, as it is in *Solen*, *Pholas*, and *Patella*.

J. GWYN JEFFREYS

OUR BOOK SHELF

The Student's Manual of Comparative Anatomy and Guide to Dissection. Part I. (Mammalia). By G. H. Morrell, M.A. (Longman and Co.)

THIS work is in two parts, which are of such different characters that they must be considered separately. The first is intended to include a short and complete summary of the main facts of the anatomy of Mammalia. This is a large undertaking, and one which a resident in Oxford has not full opportunities of completing; for the advantages in any place other than London, are not sufficient to enable any single student, however enthusiastic, to get familiar with many of the subjects discussed. There is a want of vividness and point in many of the statements, several of which are too inclusive. Referring to the lobulation of the kidneys, the seals and whales are mentioned as presenting it, but why are the ox, otter, and rhinoceros omitted? The peculiarity of the stomach of the chevrotain is not referred to, and all we can possibly infer as to that of the peccary or hippopotamus is that it is constricted into two or three portions, which is undoubtedly not enough. Half a page only is devoted to the peculiarities of the liver throughout the class, and that of man is called simple, while that of the Ruminants is included among the multifid. The spleen of the marsupials is stated erroneously to be bent or bilobed.

But the great and inexcusable imperfection of the work is the omission of the description of the generative system, which no amount of argument could persuade us will prove of the slightest good in any way. It only engenders a mystery and curiosity in the mind of the younger students, as to peculiarities of structure, which if they were treated in the ordinary routine, would, as they undoubtedly are among medical students, be looked upon in nothing but a common-place manner.

The second portion of the work, the guide to the dissections of the brain, heart, &c., of the sheep are excellent, and will be found of great value; they have long been wanted by teachers. A carefully compiled synopsis of the cerebral convolutions in man and the higher apes, from the work of M. Gratiolet, terminates the book.

Académie Royale de Belgique. Centième Anniversaire de Fondation. Two vols. (Brussels: F. Hayez, 1872.)

THESE two stout volumes, intended as a memorial of the celebration of the hundredth anniversary of the Belgian Academy, treat of a great variety of interesting and valuable matters. The Belgian Academy of Science, Literature, and Art was founded by Maria Theresa on December 16, 1772, but as December is not a very suitable month for a great public gathering of men from all parts of Europe, the Academy held its centenary fête on May 28 and 29, 1872, and it did it very royally, in presence on both days of His Majesty the King of the Belgians, who gave the opening address, and entertained members and friends on the second day in his palace at Brussels. There took part in the celebration distinguished deputies from all the countries of Europe and from America, and altogether it seems to have been a great success. In these volumes will be found a detailed account of all that was said and done, verbatim reports of all the speeches made, and of all the interesting papers read. The Academy began to make preparations for the centenary celebration in 1869 by the appointment of a commission. This commission appointed members of the various classes of science, literature and art to prepare papers giving accounts of the work done in these classes from the commencement, and others to do the same for the various literary, antiquarian, artistic and scientific subjects with which the Academy deals. From this it may be surmised that these two volumes contain matter of very great value indeed. The first paper is by M. A. Quetelet. giving a sketch (170 pages) of the history of the first century of the Academy. But the second volume will be the more interesting of the two to scientific men; we can only indicate its contents:—Astronomy in the Royal Academy of Belgium from 1772 to 1872, by M. E. Mailly; Report on the Mathematical works of the Academy during the same period, by M. J. M. de Tilly; Report on works in the Physical Sciences, Meteorology, and Physical Geography, by M. J. Duprez; Report on works in Chemistry, by M. L. G. de Koninck; Report on works in Zoology, by P. J. van Beneden; Report on works in Botany and Vegetable Physiology, by M. E. Morren; Report on works in Geology and Mineralogy, by M. G. Dewalque.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Biela's Comets

THE present note is designed to show that several comets move in nearly the same orbit with that of Biela; that they probably entered the solar system *as a group;* and that, after making their first perihelion passage in close proximity to each other, they were, when receding from the sun, thrown into their present orbits by the disturbing influence of Jupiter.

1. *Was the comet of* 1772 *identical with that of Biela?*—The mean of the seven consecutive periods between January 2, 1806, and September 23, 1852, is 2437·7 days. Counting five periods of the same mean length from February 17, 1772, brings us to July 2, 1805—six months before the perihelion passage of 1806. In other words, the mean period between 1772 and 1806 was greater by about thirty-seven days than that between 1806 and 1852. The perturbations during the half century succeeding the apparition of 1772 have not been computed. It seems very unlikely, however, that the difference of periods

could thus be accounted for. We conclude, therefore, that the comet of 1772 was not that of Biela.

2. The first comet of 1818 is regarded by Dr. Weiss as a probable member of the Biela group.* This body, discovered by Pons, was visible only four days. Its elements, as computed by Pogson, have a striking resemblance to those of Biela's comet, the longitudes of the ascending nodes differing by only 1°. There can be little doubt that it was connected, in its origin, with the comet of Biela.

3. The companion of Biela, observed in 1846 and 1852, is another comet of the same cluster. The fact that several cometary masses move in orbits almost identical, may afford a plausible explanation of the division of Biela's comet. Was one member of the group overtaken by another as they were approaching perihelion in 1845, and was their separation after imperfect collision the phenomenon observed at that epoch?

4. The comet detected by Pogson, at Madras, on December 2 and 3, 1872, may have been another member of the same family. Its perihelion passage occurred nearly three months after the time computed for that of Biela. Prof. Newton has remarked † that so great a lengthening of the period could not probably be explained by planetary perturbation.

M. Hoek has shown ‡ that certain comets have been associated in groups before entering the solar domain. When the members of such cometary systems are widely separated, they may pass round the sun in very different orbits. The comets, however, which constitute the Biela cluster must have entered our system at small distances from each other, since their orbits are nearly coincident. These orbits, between longitude 255° and 265°, pass within no great distance of that of Jupiter. The group had perhaps made its first perihelion passage in a parabolic orbit. Receding from the sun, it fell under the controlling influence of Jupiter; the comets had various positions in relation to the planet, and hence the orbits resulting from the attraction of the latter were slightly different.

We might regard the comet of 1772, the companion of Biela, and Pogson's comet of 1872, as probably identical, but for the small increase of distance between the two Biela-comets in the interval from 1846 to 1852. The period would be about 2456 days.

That the comets of this cluster have been moving in their present orbits but a comparatively short time is rendered probable by the fact that no two of the members hitherto detected have become widely separated, and that, notwithstanding the frequency of the return to perihelion, the meteoric *débris* is much less diffused than in the case of other known streams.

Were all the members of this cluster originally united in a single comet, or did they *enter the solar system* as a group? To this question, perhaps, no satisfactory answer can yet be given. It seems probable, however, that the united masses would have formed a somewhat conspicuous object, too brilliant to have entirely escaped observation.

Earthquake in Dumfries

WHILE sitting in my lonely house in a retired but beautiful glen of Dumfriesshire, I was aroused on the evening of Wednesday 16th current, at ten minutes to ten o'clock, by one of the most singular noises ever I had listened to. The tone of it was somewhat like thunder, but it did not rise and fall in pitch. It lasted, perhaps, for twenty seconds, and was accompanied by a slight tremor. At first I thought it was a two-horsed carriage coming, and at a lumbering pace, and then, with some hesitation, I took it for thunder, but next day I found that it was generally recognised as an earthquake. The shaking was very perceptible in some localities. It extended through the parishes of Closeburn, Morton, Penpont, Glencairn, and Tynron, over a length, I am safe to say, of ten miles. Dr. Grierson of Thornhilt Museum felt it as a rude shock. In Tynron village there was some alarm, as one family thought it was the wall of the churchyard that had fallen. On December 24, last year, a similar shock was felt in some parts of Upper Nithsdale. Although I have resided for many years in Dumfriesshire, these are the only occasions on which there was any surmise of an earthquake. The local papers have said almost nothing about it, but I am sure this will interest some of your readers.

East India Museum

ALLOW me to make yet another suggestion (in addition to those of P.L.S. and Prof. Newton), with regard to the disposal of the natural history collections at the India House. It seems to me to be one of the greatest popular delusions, that specimens of natural history necessarily require lofty halls and spacious galleries for their preservation and exhibition in a useful manner. I hold, on the contrary, that, with few exceptions, they far better serve educational and scientific purposes when arranged in ordinary apartments. All the scientific work in the British Museum is done in small rooms; and the palatial galleries with their crowded myriads of specimens and miles of glass cases, however instructive they may be (or might be made) to the public, are a positive hindrance to scientific work. I am very much mistaken if all the India House natural history collections might not be suitably placed in two or three ordinary sitting rooms, and so arranged in cabinets and boxes as to be far more convenient for reference and study than they have ever been. The rent of a moderate-sized house in an airy situation, say 250*l.* with an equal sum for the salary of an efficient Curator, and a small grant for cabinets and the necessary books of reference, is all the expense required to make this interesting collection completely accessible to all who wish to consult it. Every one interested in Indian natural history would then visit it. It would again receive gifts of collections from travellers, Indian Officers, and other persons interested in the natural history of the East; and its increase in value from this source alone might go far towards furnishing a tangible equivalent for the expense incurred, while it would certainly render the collection a better representation of the Indian fauna than it is at present, and more worthy of a place, at some future time, in the proposed grand Indian Museum.

Such a modest establishment would also, I believe, do much good by showing at how small an expense a really useful scientific museum may be kept up, and would thus encourage the formation of local museums in cases where 20,000*l.* or 30,000*l.* cannot be raised for a building. It would not, of course, be a show museum for the uneducated public to wander and gaze in;—the British Museum serves that purpose. But it would prove greatly superior to any such mere exhibition, as a means of furnishing definite information on Indian zoology, and enabling any intelligent inquirer to obtain some idea of the many wonderful and beautiful forms of life which characterise, what is at once the smallest and the richest in proportion to its extent, of the great zoological regions of the globe.

ALFRED R. WALLACE

IT will be greatly to be regretted if even your suggestions are adopted as a remedy for the present neglect, and the claims of scientific men and of the public at large for a Government museum be abandoned. It is very desirable for Indian interests that the Museum shall be, as before, connected with the Indian department.

It is quite true accommodation in the sky-parlours, with casual access by a lift, is given for the industrial collections so well conducted by Dr. Forbes Watson, and which collections, as chairman of the Indian Committee of the Society of Arts, I feel bound to contend for as of great value to England and to India.

There is no solid ground for letting the Government go. They acquired in the like way the property of the Levant Company, and attempted to shirk the rights and obligations, but were compelled to maintain the public buildings, churches, hospitals and burial-grounds at Constantinople, Smyrna, &c. It must be owned they constantly attempt to evade the obligations.

They are now engaged in paying off the stock of the old East India Company, of which they have acquired the territory, houses, property, prerogatives, &c., and they must simultaneously accept every obligation, pecuniary and moral.

This was a museum for the service of England and the service of India, and there is no reason why it should not be kept up. There is, it is true, a growing licence in this day for representing us as usurpers and oppressors of India, whereas the peace, prosperity, and progress of India have been created by us, and were we to withdraw, would be destroyed by the sanguinary conflicts of the various races of conquered and conquerors constituting the populations.

We ought to stand on our right to share in the prosperity of India as a prerogative belonging to us. Besides, for the benefit of India, the collections are kept up by Englishmen, for there is

not the requisite knowledge among natives in India; the work must be done in this safer climate, and the specimens can be better preserved here than in the museums of the hot plains, or those which may be formed in the damp regions of the hills. HYDE CLARKE

St. George's Square, S.W.

Instinct

Moving in a Circle

IN your last week's number a letter appeared with the initials N. Y., in which it was stated that it is believed in North America that a lost man always strays in a circle towards the left. I may mention that whilst walking in a woody and hilly part of the New Forest, I found, to my great astonishment, that I had described a complete circle, and it was towards the left. My father also tells me that he has been informed (although under what circumstances he does not recollect) that the same idea obtains in Australia. It has been suggested that the reason of this fact (if fact it is) is, that the right side of the body is stronger than the left; in confirmation of the truth of this explanation, it is worthy of notice that Dr. Wm. Ogle (in a paper on Dextral Pre-eminence, Medico-Chirurgical Transactions, vol. liv.) finds that men are right-legged as well as right-handed, although the rule has not so universal an application. One of the points adduced by him in evidence is that bootmakers generally find the right foot larger than the left.

If any of your readers who have strayed in a similar manner, would take the trouble to write to you merely stating whether they wandered to the right or the left, it is possible that a sufficient body of facts might be collected either to confirm or disprove this curious belief. GEORGE DARWIN

Down, Beckenham, April 29

Perception in Dogs

PERHAPS you will think that the following story of a Mentone dog, Pietrino, is worth adding to the similar stories which have appeared in your columns:—

The Archduchess Marie Régnier passed the winter of 1871–2 at the Hotel Victoria in Mentone. While there she became much attached to a spaniel belonging to M. Milandri, the landlord, and on her return to Vienna in the spring she took the dog there. Not long after, the dog reappeared at the hotel in Mentone, having returned on foot a distance of nearly one thousand miles over a country totally unknown, excepting having once traversed it by rail. The fatigue caused the poor fellow to die a few days afterwards, and Pietrino is honoured with a grave and a monument in the hotel gardens.

I send you a French paper containing the same facts.

JAMES B. ANDREWS

Villa d'Adhemar, Mentone, April 17

PERHAPS the following anecdote on the instinct of dogs, which has lately come to my knowledge, may prove of interest to some of your readers.

A family residing in Yorkshire possessed two dogs, one a mastiff, and the other a small dog. The owner, visiting Hastings, took the little dog with him, and at the house where he stayed there was a larger animal, who, disregarding the laws of hospitality, woefully maltreated his youthful visitor. The little dog, upon this, disappeared, and in a few days returned, bringing with him the mastiff from Yorkshire, which set upon the Hastings dog and thrashed him to within an inch of his life. Having performed this piece of retributive justice he returned to his home in the north, while the little dog stayed to rejoice over his fallen antagonist. A. PERCY SMITH

Rugby, April 18

Prehistoric Art

MR. SEARLE V. WOOD's inquiry (NATURE, vol. vii. p. 443) whether any existing race of savages is capable of depicting animals with the spirit and fidelity of the supposed contemporary representations of the mammoth is a most pertinent one, but must be answered in the affirmative. In the Atlas to Gustav Fritsch's great work on the Aborigines of South Africa, just published at Berlin, will be found reproductions of delineations of animals, executed in caves by the Bushmen, which are certainly equal to the carvings and tracings of the prehistoric period. The originals are usually painted, but sometimes carved or scratched in sandstone or some other soft material. Five different colours are employed; the objects represented are usually the animals indigenous to the country, but the human figure is occasionally introduced, and since the arrival of the European colonists, horses and even ships have been added. It is most remarkable to find the Bushmen in this respect so far in advance of the comparatively civilised negro, who has never of his own impulse produced anything approaching to the merit of these designs. Perhaps some of your contributors will be able to state whether any corresponding difference exists in the cerebral organisation of the respective races. R. G.

London, April 19

April Meteors

IN continuation of my report sent you yesterday in reference to the April meteors of this year, I desire to add the following. The evening of April 21 being clear, a watch was sustained from 9^h to 12^h, during which time 14 shooting-stars were seen. These, with the 20 observed on the two previous evenings, make the total number seen 34 in $7\frac{1}{2}$ hours of observation. The details of the meteors noticed on April 21 are as under:—

Ref. No.	Date.	Time.		Beginning. R. A.	Beginning. D.	Ending. R. A.	Ending. D.
21	April 21	9.8	$1\frac{1}{2}$ mag. *	266°	54°+	236°	32°+
22	,,	9.10	2nd mag. *	299	$38\frac{1}{2}$+	309	38 +
23	,,	9.29	3rd mag. *	310	59 +	319	58 +
24	,,	9.41	3rd mag. *	289	61 +	270	68 +
25	,,	9.57	2nd mag. *	263	50 +	238	47 +
26	,,	10.22	3rd mag. *	273	51 +	273	61 +
27	,,	10.30	4th mag. *	325	68 +	328	60 +
28	,,	10.32	4th mag. *	$264\frac{1}{2}$	61 +	255	55 +
29	,,	10.50	4th mag. *	319	$69\frac{1}{2}$+	339	66 +
30	,,	11.7	α Lyræ	$295\frac{1}{2}$	45 +	309	49 +
31	,,	11.16	3rd mag. *	278	49 +	270	$59\frac{1}{2}$+
32	,,	11.32	4th mag. *	275	14 +	283	12 +
33	,,	11.40	3rd mag. *	284	59 +	270	47 +
34	,,	11.45	4th mag. *	334	47 +	341	41 +

Nos. 22, 25, 26, 30, and 31 were from the radiant near α Lyræ. On April 19 and 20 the largest proportion of meteors were Lyraïds, but on April 21 they were in a minority. Nos. 21, 23, 24, 33, and 34 were conformable to a radiant at ο Draconis, R.A. 283°, D. 59°+, and it is worthy of note that on the two preceding nights there were no indications of this radiant point. To sum up my recent observations, it would seem that from the various meteoric tracks noted, the April shooting-stars of this year had three well-marked centres of radiation, viz., (1) near α Lyræ, (2) near Arcturus, and (3) at ο Draconis (R.A. 283°, D. 59+). There were also evidences of at least two other radiant points that, owing to the paucity of meteors, could only be approximately ascertained, viz., (1) near ζ Draconis, and (2) near α Cygni. The brightest meteor seen on April 21 was a Lyraïd; time, 11^h 7^m. Its path was accurately fixed. The meteor first appeared at 1° N. of δ Cygni, and travelling to N., disappeared in a small triangle of stars 5° N. of α Cygni. Several of the meteors emitted sparks in traversing their courses, but the majority were small objects of very brief duration.

The foregoing particulars (taken in conjunction with my previous letter) may be useful in determinating the radiant point of the April meteors, especially with regard to those diverging from Lyra, which, I believe, are considered identical with Comet I. 1861. I fixed this point at R.A. 274°, D. 37+, which is nearly of accord with the result of Karlinski (1867), R.A. 278°·2 D. 34°·5+, and of Prof. A. Herschel (1864), R.A. 277°·5, D. 34°·6+.

Bristol, April 22 WILLIAM F. DENNING

A proposed new Barometer

IN the number of the *Philosophical Magazine* for May 1871 is an article by Prof. Heller, of Ofen, rendered (carelessly enough) from Poggendorff's *Annalen*, describing a balance fitted with nearly equal weights of very different volumes, which he proposes as a barometer. He says that the principle on which it is founded "has not hitherto been used in barometric measurements." This is not quite correct; a balance, absolutely identical in principle, is described by Boyle in vol. i. p. 231, of the Philosophical Transactions, under the title of "A new Statical Baroscope." It would seem that the practical difficulty of keeping it in accurate adjustment has been and still will be a bar to its use in the way the two inventors have proposed; otherwise, it might perhaps be advantageously employed in mountain surveys; it would, at any rate, be free from many of the objections to the aneroid.

Considered, however, as an exact barometer, I would main-

tain that the principle is altogether erroneous, depending as it does on the assumption that the pressure of the atmosphere is purely a function of its specific gravity or density. This is not true, for pressure may vary within wide limits, whilst the density remains unchanged. Experimentally this might be shown by putting, say, an aneroid and a balance, such as I have been speaking of, in a large glass vessel, which can be made air-tight when closed. Under normal conditions the two will at first register the same pressure; but if the temperature is sufficiently increased or diminished, the increase or diminution of elastic force will manifest itself by the aneroid; but as the density remains unaltered, the balance will show no change. Does such an experiment at all correspond with any natural observations? I think so, in, of course, a limited degree. If the lower part of a column of air is heated, its expansive force will push the adjacent air outwards and upwards; but as it does so, it has to overcome a certain amount of inertia; to do this requires time, during which, as the volume of the heated air does not increase in proportion to the temperature, the elastic force does. This ought to be shown by the barometer; I think it often is, but the barometer is a sluggish instrument at best, and its indications are undoubtedly wanting in quickness, and therefore in exactness. Still its principle is correct; so is the principle of the aneroid, or of Bourdon's barometer (on which there is an interesting paper in the *Quarterly Journal* of the Meteorological Society for April 1872), though practical difficulties stand in the way of their use becoming general. But the tangent balance is not capable of measuring atmospheric tension, except when that tension depends on density alone; and this is frequently not the case—perhaps never.

April 23

Acquired Habits in Plants

AT p. 446 of NATURE, J. G. records a "dog violet" which he thinks has assumed an unusual form. As there are several plants called "dog violet," and as one of them does in favourable situations attain a very considerable height, it would be interesting to know what was the species observed by the river Aled. The *Viola canina* (*V. riviniana* Reich.), in one of its forms which is probably a distinct species, has flowering shoots which sometimes attain a foot in length, and if supported by the surrounding vegetation do sometimes stand nearly upright. If this was the plant observed, J. G. only found a more than usually strong form.

C. C. BABINGTON

The Zodiacal Light

MR. BACKHOUSE asks if the observations given in vol. iii. p. 203, afford any proof that the Zodiacal Light is not a lens-shaped disc of light enveloping the Sun; if this theory were correct, and the sun enveloped in a continuous mass of light-reflecting matter, whenever the light is seen in the evening after sunset, it ought to be also seen in the morning before sunrise, of the same brilliancy at the same angular distances from the sun, especially when those distances are small, for then the effect of an elliptical form in the section of the envelope by the plane of the ecliptic would be almost entirely eliminated.

The results of observation given in most of our hand-books of astronomy are therefore directly at variance with this theory, and I did not consider it necessary to allude to it before.

Jamaica, April 6 MAXWELL HALL

ON VENOMOUS CATERPILLARS *

POISON and venom are often used as convertible terms. I do not understand them to be so. Poison properly means something which injures the system by introduction through the stomach. Venom, something which injures by introduction into the vascular system through lesion of the tissues. Most poisons are also venoms; whatever injures, if introduced into the stomach, will most probably also injure if introduced directly into the blood. But the converse is not true: most venoms are not poisons, that is, it is not by digestion and assimilation that they work, but by entering the vascular system from without. It is said that you may swallow the venom of the rattlesnake with impunity; and I imagine you may, if it does get absorbed through the mucous membrane; but Dr. Fayrer's experience, lately published, of the effects of the semi-swallowing, which occurs in extracting the venom from a poisoned wound by sucking, would rather seem to show that such extremely virulent venom would penetrate the mucous membrane, and act as if actually introduced by a wound, his throat having become dangerously ulcerated from sucking the poison from the wound of a man bitten by a cobra. There is yet another way than swallowing or being wounded, by which venom may injure, and that is through the nervous system, by application to the skin. This is the way in which the nettle must sting. In that case there is not the smallest lesion in the skin, and if a nettle were artistically made to touch the open surface of a gaping wound, it would not sting at all; neither is it by mechanical irritation that the pain is caused. The nettle has a venom gland, as well as the rattlesnake, and it is the application of this venom to the delicate termination of the nerves in the skin which produced the pain felt.

The subject to which I invite the consideration of the Society this evening is whether any insects possess similar power of injury to that of the nettle. In ordinary cases the venom of insects is applied by a puncture in the skin, into which the venom is introduced by an apparatus provided for the purpose. But for a long time it has been said that certain caterpillars sting like the nettle, although the authorities have for the most part been too vague to allow us to be very sure as to the fact; and supposing the fact to be true, it has been argued that the pain or annoyance was merely the result of mechanical irritation of a similar nature to that which medical men sometimes meet with in hairdressers, or rather haircutters, where minute portions of the cut hair of their customers work their way into the skin below the shirt-sleeve and give rise to a painful and irritating sore on the wrist. Two passages which I shall take leave to quote, will bring the question, as it at present stands, pretty fairly before the meeting. The first is from a paper by myself on the geographical relations of the chief Coleopterous Faunas, which was published in the Linnæan Society's Journal for 1870 (p. 55):—

"A very remarkable African affinity in the Lepidoptera has been mentioned to me by Dr. Welwitsch. It is plain that an affinity to any genus endowed with peculiar properties is rendered doubly certain if the supposed allied species possesses the same properties. There is a Lepidopterous insect in Australia, the larva of which possesses remarkable poisonous powers. It has been named *Doratophora vulnerans*. Such insects also occur in South Africa. Livingstone speaks of a caterpillar called *Rigura* as producing fearful agony if a sore is touched with its entrails. Mr. Baynes, in his "Explorations in South-west Africa," speaks of another, or perhaps the same, which he calls the *Kaa*, and which is used as a poison for their arrows by the Bushmen; and Dr. Welwitsch had a personal experience of the severe swelling and pain in every part of his body which he touched with his hand after collecting specimens of a caterpillar against which he had been warned as poisonous. He had in consequence of the warning carefully avoided touching them, shoving them into a phial with a straw; but whether he had inadvertently touched them or fingered the leaves on which they had been feeding (which he collected for examination), he and his servant were both laid up helpless for two or three days. His specimens of the caterpillar were lost; but among his Lepidoptera Dr. Fendler of Vienna, who has undertaken a description of them, finds no less than four species of *Doratophora*, and these, doubtless, are the perfect insects of species of the caterpillar, from one of which he suffered."

The second passage which I wish to quote is from a paper by Mr. Roland Trimen, Notes on the above paper, and also published in the Linnean Society's journal. It is as follows:—

"At p. 55 Mr. Murray notes what he considers 'a very

* A paper read at the opening of the Kensington Entomological Society.

remarkable African affinity' in the Lepidoptera of Australia, in reference to the case of the larva of *Doratophora vulnerans* Lewin. The instances which he cites as analogous, however, are very different in character, for he quotes the mention by Livingstone 'of a caterpillar called *Rigura*, producing fearful agony if a sore is touched *with its entrails*'; and the statement made by Baynes and other travellers, that a caterpillar is used by the Bushmen to poison their arrows. It is evident that, if a caterpillar be used at all for poisoning arrows (concerning which report my inquiries have hitherto been attended by no satisfactory result) it must be the intestines or juices of the animal which are so employed. But the case of *Doratifera vulnerans* is the common one of (what appears to be mechanical) irritation, by means of clusters of spines, a defence possessed by many caterpillars, not only in Australia and South Africa, but throughout the globe, and of which the larva of the European *Cnethocampa processionea* presents a familiar example. Duncan (Nat. Libr. Ent. vol. vii. Exotic Moths, pp. 181-2. pl. xxii. f. 5) represents the larva of *D. vulnerans* as possessing four fascicles of rufous spines, exsertile at will on both the anterior and posterior portions of the body, and quotes Lewin to the effect that the wound inflicted by the fascicles is very painful. According to Mr. Murray's account it would appear that the African larvæ, from the handling of which Dr. Welwitsch experienced such suffering, were near allies (if not actually species of *Doratifera*); and the conclusion is obvious that it was by fascicles of spines that the pain was occasioned—not an uncommon case in the warmer parts of the world, and one by no means indicative of any special relation between the Lepidopterous faunas of South Africa and Australia."

Mr. Trimen is obviously right as to the absence of analogy between the venomous properties of the caterpillars spoken of by Livingstone and Baynes, and those met with by Dr. Welwitsch, and it was a slip on my part to collocate them together; but I am not satisfied that he is equally right in referring the pain caused by the species of *Doratophora* to mechanical irritation. He gives no facts in support of his assumption to that effect, and the facts communicated to me by Dr. Welwitsch regarding the insect from which he suffered seem to me wholly inconsistent with that supposition. It may be supposed from his and my silence that we acquiesced in Mr. Trimen's views. But it is not so. When Mr. Trimen's paper appeared Dr. Welwitsch spoke to me upon the point, and I urged him to communicate to the scientific world fuller details of the incident than I had given, and I understood that he intended to do so in any account of the insects collected by him. I therefore did not feel warranted in speaking, which I now regret, for as with much else that he had on hand to do, his life has been too short for him to do it himself. Now that he has passed away from us I should not like an erroneous impression to exist as to the facts; and although I have little to add to what I formerly stated as communicated by him to me, I should wish to repeat it more precisely, and to say that Dr. Welwitsch himself was firmly convinced that it was not a case of mechanical irritation but of a special virus of unusual potency.

In the first place, then, Dr. Welwitsch had heard of this noxious caterpillar before he met with it—the natives knew it well and dreaded it. In the next place when he did meet with it his native attendant warned him of it—and they took every precaution against touching it; they plucked leaves on which the caterpillars were feeding and guided them from the leaf into the wide-mouthed bottle or vessel he had to carry such specimens home in. They also took specimens of the plant on which they were feeding. I suggested to him that the sting might have been in the plant, but this he was positive was not the case. The virulence of the venom was such that by the time they reached home in an hour or so after, every tender part of their body which they had touched with their fingers had become swollen and inflamed; their eyes were closed up, their lips and cheeks swollen as if they had been assisting (as principals) at a prize fight, and the consequent fever was so great that they were laid up, unable to move for two or three days; and when they did get up he found that their attendants had bundled out of the house both the caterpillars and the plants on which they fed. Now it seems to me that mechanical irritation is a wholly inadequate cause for such extreme inflammatory action. Mechanical irritation may go a certain length, but there are bounds beyond which we must look for some other explanation.

But first we want more facts and more examples. I exhibit two caterpillars, apparently different species, which I have received from Old Calabar, given to me with a notandum as reckoned injurious if not venomous, but my information as to them is too vague to allow me to cite them as positive examples of venomous caterpillars. And I also show one from Brazil which I have received from my friend, Mr. Fry, which he informs me bears a very bad character in Brazil. Both of these, indeed, all to which this property has been ascribed, are hairy caterpillars; but then it is only hairy caterpillars that seem to have the necessary apparatus for stinging—all stinging plants, so far as I know, are hairy. If the caterpillars have a special venom, then, as in the nettle, there should be a gland at the base of each hair, which should be hollow, and the spines in most, if not all, our caterpillars are hollow. I know of no physiological reason against their being so made. In the skin of the newt there are pores which exude an acrid irritating fluid. If a hollow hair were placed over the pore with proper muscles, we should then have a parallel to the supposed case.

But, as I said before, we want information as to the existence and amount of this venomous property, and the chief object of this paper to-night is, after eliciting the views of the meeting, to suggest to those who may have the opportunity, the desirableness of making observations on the point.

A. MURRAY

ON SPACE OF FOUR DIMENSIONS

WE may define *space* as that which indicates and measures the extension of the Universe. We may determine the form and position of any material object by assuming three infinite planes, fixed in infinite space, and at right angles to each other. Space then is the room occupied by matter, or included between distant masses of matter; and, as such, we know of it only as possessing three dimensions—length, breadth, thickness.

Descartes (*Principia* pars. 2, "*Quid sit spatium, sive locus internus*") remarks, "For, in truth, the same extension in length, breadth, and depth, which constitutes space, constituted body; and the difference between them consists only in this: that in body we consider extension as particular, and conceive it to change with the body; whereas in space we attribute to extension a generic unity (*genericam unitatem*), thus after taking from a certain space the body which occupied it, we do not suppose that we have at the same time removed the extension of the space, because it appears to us that the same extension remains there so long as it is of the same magnitude and figure, and preserves the same situation in respect to certain bodies around it, by means of which we determine the space."

Gauss used to say that one of the happinesses of his future life would be the amplification of his conceptions of space; the realisation of that which he had once known as space of three dimensions, as space of four dimensions. For just as we can conceive of beings "like infinitely attenuated book-worms in an infinitely thin

sheet of paper," which can realise space of only *two* dimensions, so also we may conceive of beings capable of realising space of *four* dimensions. Prof. Sylvester, Dr. Salmon, Prof. Clifford, and others, have indicated in some of their profoundest mathematical demonstrations that they possess "an inner assurance of the reality of transcendental space." We desire now to bring forward, with great apology to the mathematicians for our temerity, some ideas, which we believe may enable even the least mathematical amongst us, to realise,—faintly, indeed, and very dimly—the possibility of existence of space, other than that which we now occupy. This we propose to do, (a) by attempting to realise a condition of life in space of two dimensions, and (β) by adding the element of diverse motions, to our already known space.

Our knowledge of the Universe involves the conception of *space*, *time*, and *number*. These are intuitive notions: we cannot strictly define them; in the abstract our notion of them is merely relative; apart from material existence we cannot realise them. Extension is an essential property of matter, and our conception of space is linked with our conception of extension. Robert Hooke, in a series of lectures *De Potentia Restitutiva*, written nearly two hundred years ago, and too little known, defines a sensible body as "a determinate space, or extension, defended from being penetrated by another, by a power from within." Now this power may be most readily conceived to be a vibratory motion of the particles across a position of rest. Let us imagine an infinitely thin plane vibrating between two fixed points with such velocity that no other matter can penetrate into the space limiting the vibration, then a solid bounded in one direction by the two fixed points would be the result. For example, let an infinitely thin sheet of iron a metre square vibrate with extreme velocity in a span of one metre, and a cubic metre of iron would be the result. The rapid vibration of the plate would defend the range of vibration from being penetrated, and impenetrable material substance would result. An infinitely thin line vibrating between two fixed points would furnish a plane. An infinitely thin plane vibrating between two fixed points would furnish a solid. Thus by the addition of motion we can convert a determinate space, approximately of one dimension, into space of two dimensions; and by the addition of motion we can convert space of two dimensions into space of three dimensions. Can we conceive of any motion which given to space of three dimensions shall generate space of *four* dimensions? We do not know of such motion, but we can surely conceive the possibility of its existence. Space of four dimensions is transcendental space: it is beyond the limit of our experience, but not beyond the limit of our imagination.

Let us now endeavour to realise the condition of a being living in space of two dimensions. If man possessed the eyes and the power of flight of an eagle, superadded to his ordinary intellectual qualities, he would, no doubt, have very enlarged views of space. As it is, man is distinguished from the brute animals by his erect bearing, and the range of space which his vision enables him to scan. Our eyes are easily movable in various directions, so also is our head; by a slight movement of the head and eyes, we may take in either space bounded by the horizon, or by a surface a foot square. If we throw our head back we enlarge our view of space; if we bend our head forward we narrow our view of space. Now, imagine that a man thus endowed, and with our own notions of space of three dimensions, begins to stoop forward and to grow so: his eyes survey less space; he stoops more forward; his body forms angles of 80°, 70°, 60°, 50° in succession, with a horizontal plane. Then he is obliged to go on all-fours, his limbs shorten and are gradually absorbed into the mass of his body; he crawls, he creeps; at length his limbs disappear altogether, and he trails himself along and glides like a serpent, moving in a horizontal plane. During these successive shrinkings in the direction of his thickness his head has become fixed, his eyes motionless, in the plane in which he moves, and his vision has hence become more and more limited. Now his body begins to diminish in thickness; he becomes thinner, and thinner, and thinner, and when he has become very thin indeed, let his thickness be expressed as the numerator of a fraction, while the denominator is an infinitely great number—say, if you will, as many figures as, written on paper, would reach ten billion miles, with ten figures to an inch. Now he is a mere plane, an infinitely thin surface; he occupies space approximately of two dimensions; his eyes are on a line. Try to imagine what the ideas of space of such a being would be; compared with our own ideas of space, compared with his own ideas before and during his process of flattening. He would now contemplate only a plane surface; he would see length and breadth without thickness. Compare also his ideas of space at each and every position between verticality and horizontality as his ken gets less and less, and at last the whole world is shut out from him.

Again, to come nearer home, and back again to the world of real existences, let us compare our own ideas of space after concentrating our vision for awhile on a book a foot square, with our ideas of space acquired while we ascend a lofty mountain, or lie upon our back on the deck of a vessel in mid-ocean. Compare the views of space possessed by a prisoner immured for forty years in a dungeon eight feet square, of La Sachette in the *Trou aux Rats*, of a being bed-ridden for half a century, with those of a hunter in the prairies of the West, a sailor of the Atlantic, even of a dweller in a flat tame country. The conceptions of space possessed by these different people will vary enormously. Contract the limits of space of possible contemplation; remove the possibility of contemplating space of great dimensions, and the *faculty* of such contemplation will itself die out; and thus, by a gradual process of diminution, we may arrive at our ideal being, living in space of two dimensions. Finally, let us imagine the being of two dimensions—length and breadth—to become narrower and narrower, and when he has become extremely narrow let us divide his breadth by an infinitely large number, and he becomes approximately of one dimension; he has now only length; he lives in a line; his one motionless eye is a point.

So much for space of less dimensions than our own. Let us now try to conceive an extension of our ordinary space; and let us attempt this by the superaddition of motion to known space. And let us clearly realise the fact that one and the same thing may easily possess various motions at the same time. For instance, when I walk across the room, talking the while; my vocal chords possess *five* distinct motions: (a) their own proper motion of vibration; *plus* (β) the motion of translation caused by walking forward; *plus* (γ) the motion of rotation of the earth about its axis; *plus* (δ) the motion of revolution of the earth about the sun; *plus* (ϵ) the motion of translation of the whole solar system through space. Let us suppose now that our bodies, instead of being at apparent rest, were to vibrate in arcs, with an amplitude of 10,000 miles, and with an infinite velocity; and let the plane of the direction of vibration itself vibrate between limits 10,000 miles apart; and let the whole vibrating system move with infinite velocity in a circle 1,000,000 miles diameter; and let the circle rotate upon its diameter; and let the sphere of revolution thus formed revolve in an infinitely great ellipse; and let the ellipse rotate upon one of its axes; and—— but hold! we have surely arrived at a somewhat enlarged view of our own relations to space. Conceptions of this nature sufficiently pursued may, perchance, lead us to the very threshold of transcendental space; and, once on the threshold, we may look wonderingly beyond.

G. F. RODWELL

ON THE SPECTROSCOPE AND ITS APPLICATIONS

VIII.

I TOLD you I had something more to say about the spectrum of blood, and this is not only an instance of the way in which the spectrum helps us in several important questions that, at first sight, do not seem at all connected with each other, but it shows the enormous power of research that is open to us. The colouring matter of blood, for instance, is found, like that of indigo, to exist in two perfectly different states, which give two perfectly different spectra. The colouring matter of blood is indeed capable of existing in two states of oxidation, which are distinguishable by a difference in colour, and also in their action on the spectrum. They may be made to pass one into the other by suitable oxidising and reducing agents; they have been named by Professor Stokes, their discoverer, red and purple cruorine. Previous to the introduction of spectrum analysis, red and purple cruorine were perfectly unknown. Further, if by means of a spectrum microscope, such as I have already described, a blood-stain is examined, Mr. Sorby asserts that the thousandth part of a grain of blood, —that is to say, a blood-spot so small that it only contains $\frac{1}{1000}$ of a grain, is perfectly easy of detection by means of this new method, and he has shown that its presence may be easily proved in stains that have been kept for a long time, and recognised even after a period of fifty years.

FIG. 46. FIG. 47.
Fig. 46.—Steinheil's slit, showing reflecting prism. Fig. 47.—Path of light through reflecting prism and into the slit.

He has also shown how it may be detected under the most unfavourable conditions, provided that a trace of hæmatin has escaped decomposition or removal; he has, in fact, successfully applied this method in several important criminal cases.

Another very interesting fact is, that when blood contains very small quantities of carbonic oxide gas in solution, it exhibits a very curious series of absorption bands. This fact is of considerable value in toxicological research, for in cases of poisoning by the so-called charcoal fumes, where, as is well known, the poisonous action is due to the formation of carbonic oxide, it can be readily detected by the peculiar bands which the blood under these circumstances exhibits.

Mr. Sorby has also applied the spectrum microscope to the study of blow-pipe beads, and has shown that in some cases as small a quantity as $\frac{1}{10000}$th of a grain of some substances can be thus recognised, even when mixed with other coloured bodies, which would interfere with the usual reactions dependent on colour alone.

In the case of radiation, as you know, we are able to determine the existence of new elements altogether. This is produced to a certain extent, as in the above case, in the absorption spectrum. Let me give you another practical application of this principle. Dr. Thudichum, as a result of researches made for the Medical Department of the Privy Council, has communicated to the Royal Society a paper in which he narrates the result of his inquiries on the yellow organic substances contained in animals and plants; and at the present moment it is impossible to say what important practical results may be expected as we come to know more about these substances, especially in the matter of dyes, which I am sure is a thing that will commend itself to you.

Again, Mr. Sorby, in a communication to the Microscopical Society, brings the matter still nearer home. He shows us that, in the case of wines, he can, by means of the absorption bands, determine the very year even of vintage, and this, you will see at once, is a matter of very great importance. Let me read you an extract from one of Mr. Sorby's reports. He says :—" The difference for each year is at first so considerable that wines of different vintages could easily be distinguished; but after about six years, the difference is so small that it would be difficult or impossible to determine the age to within a single year. After twenty years, a difference of even ten years does not show any striking contrast, and the age could not, therefore, be determined to nearer than ten years by this process. However, up to six years I think it quite possible to determine the age to within a single year. I took specimens of various ports from the casks, of different ages up to six or seven years, and labelled them in such a manner that I did not know the age of any, but could ascertain it afterwards by reference. I then made the experiments with great care, and found that, by proper attention to the details described above, I could correctly determine the year of vintage of each particular specimen." (*Chemical News*, December 17, 1869, p. 295.)

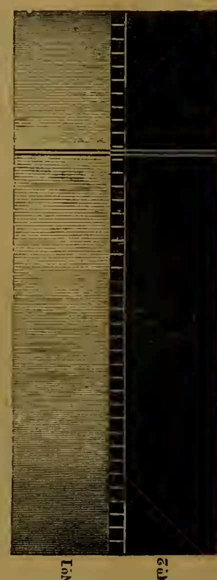

FIG. 48.—Coincidence between the bright line given out by sodium vapour and the dark line produced by the absorption of sodium vapour.

We have, in fact, a definite method of analysis of animal and vegetable colouring matter, and also of the colouring matter of decayed wood. Nor is this all, for, in another communication—for these things are now beginning to crowd upon us, and they will continue to do so much more by-and-by—Dr. Phipson asserts that this new method is perfectly competent to indicate any ar i-

ficial coloration of wine. Mr. Sorby, on the other hand, has given his attention to beer; so that you see, if I have been taking you occasionally to the stars, I sometimes have the opportunity of travelling a great deal nearer home.

Mr. Sorby has also made some extremely delicate and interesting researches on the colouring matters existing in leaves. He has been able to identify numerous colouring principles, which he has arranged in five distinct groups: these groups rejoice in the names of chlorophyll, xantophyll, erythrophyll, chrysophyll, and phaiophyll, the absorption spectra of which are perfectly distinct and well marked. It is found generally that leaves contain colours belonging to several groups, and frequently more than one of the same group. Mr. Sorby also finds that the change of colour which takes place in autumn consists chiefly in the disappearance of the chlorophyll, which renders the remaining colours visible, and these most frequently are of a yellowish tint. Some leaves, however, turn red in the autumn: this appears to be due to a falling off of the vital power of the plant, for by artificially diminishing the vital power, the intensity of this red colour is increased.

One great value of this method of research is that it enables us to recognise special colouring-matters, even when mixed with several others, and to determine the particular conditions in which they occur in plants or animals—whether in a solid state or in solution—and whether those dissolved out by reagents exist as such in the living organisms, or are the products of decompositions.

So that you see, on the whole, at the present moment, I think we may be full of hope that the new process may gradually lead to many more practical applications; but really we cannot say much about them at present, because the introduction of spectrum analysis is so recent. We are, however, already furnished with another instance of the close connection there always must be between any great advance in physical inquiry and the application of the skill of our opticians to aid us in the inquiry. We have the Sorby-Browning spectrum microscope, and then a large number of people can study the beautiful phenomena which this new method of research has opened up to us, where formerly it was almost impossible to imagine that science, or even the practical affairs of earth, should in any way benefit.

Having thus dealt very briefly with some of the more practical applications of the subject, I must now take you a somewhat distant journey to the sun and to the stars; and I must, in the first instance, attempt to connect the two perfectly distinct classes of phenomena which I have brought to your notice,—the phenomena, namely, of radiation, and the phenomena of absorption; and this con-

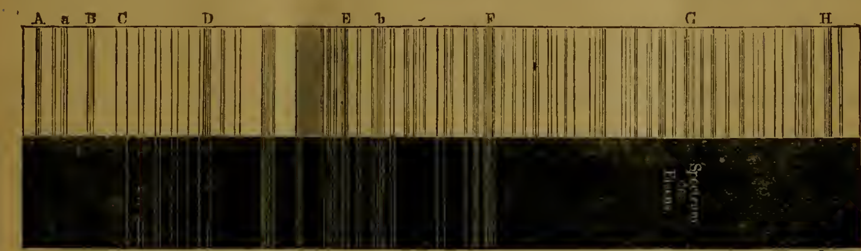

FIG. 49.—Correspondence of some of the lines given out by iron vapour (below), and of some of the Fraunhofer lines in the solar spectrum.

nection between radiation and absorption is an instance of the slow growth of science. I remarked to you in the former lecture, that Fraunhofer, at the beginning of this century, had a very shrewd suspicion of the perfect coincidence of place in the spectrum between certain dark lines which he saw in the spectrum of the sun, which I promised to explain to you on this occasion, and the bright lines in the spectrum of sodium. You know how very simple the spectrum of sodium is: you will, perhaps, think it very strange indeed that such a simple thing was not explained very long ago. But Fraunhofer at the first suspected, and after him many of our greatest minds suspected, that there was some hidden, wondrously strange, connection between the double yellow line which you will remember is characteristic of sodium, and a certain double line which exists among the strange black lines of the solar spectrum, which I begged you to banish from your minds on the last occasion, when we were merely dealing with radiation. But now I must ask you to bear with me while I attempt to make clear to you all the strange facts concerning these black lines. I have been favoured by Dr. Gladstone with an extract from Dr. Brewster's notebook, dated St. Andrews, October 28, 1841. In it Brewster says:—"I have this evening discovered the remarkable fact that, in the combustion of nitre upon charcoal, there are definite bright rays corresponding to the double lines of A and B, and the group of lines *a* in the space A B. The coincidence of two yellow rays with the two deficient ones at D, with the existence of definite bright rays in the nitre flame, not only at D but at A, *a* and B, is so extraordinary, that it indicates some regular connection between the two classes of phenomena." The double lines A and B refer to some of these dark Fraunhofer lines in the solar spectrum, which for convenience of reference were at first called after the letters of the alphabet; we now find that their number is so enormous that it is absolutely impossible to attempt to grapple with them in any such method, but these names are still retained.

The explanation of the coincidence between the two bright lines of burning sodium vapour and the two dark lines D in the solar spectrum was first given by Prof. Stokes about 1852.

It is this. The light emitted by an incandescent vapour is due to the vibrations of its molecules, as a sound note emitted by a piano wire is due to the vibration of the wire. You have only to go into a room where there is a piano, and sing a note, to find that the wire which corresponds to your note will respond to your voice. Now, in the same way, when light is passing through a vapour, the molecules of which vibrate at any particular rate, they will be urged into their own special rate of vibrations by the vibrations of the light which correspond to that particular rate which is passing through them. Hence the light will, so to speak, be sifted, and the force it has exercised in impelling the particles in the interrupting vapour to vibrate will tell upon it; and in this way those particular vibrations which have had the work to do will be enfeebled.

It is clear that the parts of the spectrum thus reduced in brilliancy will depend upon the vapour through which

the light has passed. If sodium vapour be traversed, then the light corresponding to the bright lines of sodium will be enfeebled.

This great law, to which the researches of Stokes and Stewart and Angström have led, and which has been established by the experiments of Foucault, Kirchhoff, and Bunsen, may be summed up as follows:—*Gases and vapours, when relatively cool, absorb those rays which they themselves emit when incandescent*; the absorption is continuous or selective as the radiation is continuous or selective.

J. NORMAN LOCKYER

(*To be continued.*)

NOTES

THE Emperor of Brazil has conferred upon Dr. Warren De La Rue the distinction of Knight of the Imperial Order of the Rose.

THE subject of Professor Tait's Rede Lecture, to be delivered on the 23rd inst., will be "Thermo-Electricity."

A PARAGRAPH has recently appeared in several scientific papers quoted from the *Zeitschrift für Parasitenkunde*, stating that Prof. Hallier of Jena has described a new potato-disease, which made its appearance last autumn in the neighbourhood of that town, the disease being indicated by the presence of a purple web and the appearance of a number of black spots on the skin, referable apparently to the perithecia of a pyrenomycetous fungus. We learn from the Rev. M. J. Berkeley that this so-called new disease is nothing but the well-known "copper-web" which is in some years very destructive to asparagus, mint, and other crops, and has been known in some instances to attack the potato. The description in the *Zeitschrift* is identical with this familiar parasite. Figures will be found in Tulasne's "Fungi Hypogæi," under Rhizoctonia, showing that the so-called perithecia are spurious. Mr. Broome has detected the form of fructification known as conidia.

LADY LYELL, wife of Sir Charles Lyell, Bart, F.R.S., died last Thursday, in her 65th year. Her ladyship was the eldest daughter of the late Mr. Leonard Horner, F.R.S.

DURING the Easter term the following lectures in natural sciences will be given at Cambridge:—On Heat (1) Advanced (for the Natural Sciences Tripos), by Mr. Trotter, Trinity College, in Lecture-room No. 11, on Mondays, Wednesdays, and Fridays at 10, commencing Wednesday, April 30 (2) Elementary (for Special Examination and 1st Part of Natural Sciences Tripos), on Tuesdays, Thursdays, and Saturdays at 11, commencing Tuesday, April 29. On Chemistry, by Mr. Main, St. John's College, on Tuesdays, Thursdays, and Saturdays at 12, in St. John's College Laboratory, commencing Thursday, April 24. Instruction in Practical Chemistry will also be given. On Palæontology—the Mollusca, &c., by Mr. Bonney, St. John's College, on Tuesdays and Thursdays, at 9, commencing Thursday, April 24. On Geology—(for the Natural Sciences Tripos, Stratigraphical Geology), by Mr. Bonney, St. John's College, on Mondays, Wednesdays, and Fridays, at 10, commencing Wednesday, April 23. Elementary Geology (for the First part of the Tripos and the special examination), on Tuesdays and Thursdays, at 11, commencing Thursday, April 24; there will be excursions, of which notice will be given from time to time. On Botany (for the Natural Sciences Tripos), by Mr. Hicks, Sidney College, on Tuesdays, Thursdays, and Saturdays, at 11, in Lecture-room No. 1, beginning on Tuesday, April 29; the lectures during this term will be chiefly on Cryptogamic Botany and on Classification. Biology: the Trinity Prælector will give a course of Practical Lectures on Elementary Biology, on Mondays, Tuesdays, and Wednesdays, at 11 A.M., commencing Wednesday, April 30. This course is intended as an introduction to the study of both anatomy and physiology. A short lecture of about half-an-hour will be given at each meeting, followed by practical work for about 1½ or 2 hours.

THE annual *soirée* of the Royal Society last Saturday at Burlington House was a great success. The number of visitors was exceedingly large, and the objects exhibited were numerous and varied. In the Mathematical Room, Mr. Latimer Clark showed his remarkable experiment of the influence of light on the conductivity of selenium, recently described in NATURE.

THE office of "Lord Rector" of a Scotch University is generally regarded as merely honorary, a testimony of the estimation in which the students hold the gentleman whom they elect. As a rule the Lord Rector acquiesces in this opinion, and seldom does more in return for the supposed honour conferred than mark the commencement or close of his three years' tenure of office by making a speech to the students. As might be surmised, Prof. Huxley, who was recently elected to the Lord Rectorship of Aberdeen University, which counts Prof. Bain among its staff of teachers, does not regard the office as merely honorary: he intends to take advantage of the position conferrred upon him by doing some actual work for the good of the University. Naturally one of the first grievances he has attacked is the medical curriculum, which at Aberdeen, as at most other medical schools, is hampered by the "traditions of the elders" as to the supposed advantages of the dead languages to a medical student. Shortly after Prof. Huxley's election, he received a numerously signed petition from the medical students requesting him to use his influence to obtain the omisssion of Greek as a compulsory subject in the preliminary examination. Prof. Huxley has given notice that he will bring forward at the next meeting of the University Court a resolution to reform the medical curriculum at Aberdeen, as he considers it at present rather overweighted with classics, and believes that some new arrangement would probably be exceedingly advantageous, especially in the matters of natural history and botany.

WE hear from Mr. Lloyd that living specimens of the Lancelet (*Amphioxus lanceolatus*) have been very recently received at the Crystal Palace Aquarium, from Naples, and are now alive. We hope that Dr. Dohrn will be successful in sending other living specimens of this most interesting fish to other Aquaria in this country, so that its affinities and development may be more thoroughly worked out and generally understood.

MR. THOMAS WILLIAM BRIDGE was on Friday elected to a Natural Science Scholarship at Trinity College, Cambridge. Mr. Bridge has for some two years worked under Mr. J. W. Clark, the Superintendent of the University Museums of Zoology and Comparative Anatomy, and about a month since was appointed, by the Professor of Zoology, to the newly-founded post of Demonstrator in Comparative Anatomy in the University.

DR. DIVERS, of the Middlesex Hospital, has been appointed to the Professorship of Chemistry in the new Engineering College at Jeddo.

PROF. AGASSIZ has not been behindhand in employing the advantages placed at his disposal by Mr. Anderson's munificent bequest. A programme is already published of a summer course of Natural History at Penekese Island, designed chiefly for teachers, and for students preparing to become teachers. Among those that Prof. Agassiz is able to include on his staff we find the names of Profs. Shaler, Wilder, Packard, and Putnam, and every attempt is being made to obtain a sufficient endowment, through the liberality of others, to offer the course free of charge to deserving students. The Superintendent of the United States Coast Survey and the United States Commissioner of Fisheries have also promised all the assistance in their power to this excellent undertaking.

Dr. Charles C. Abbott has discovered in the river drift at Trenton, New Jersey, in gravel at great depth, and beneath undisturbed layers of fine sand, three chipped implements, of unquestionably human manufacture, lying close to each other. One has a knife-like form, 9 in. long, made of a reddish-brown stone, compact, laminated, and susceptible of a high polish. The other two bear a considerable resemblance to common European forms: one is of opaque yellowish quartz, $5\frac{1}{4}$ in. long, and $1\frac{1}{2}$ in. in greatest width; the other is a flake of sand-stone rock, $6\frac{1}{2}$ in. long, $3\frac{1}{2}$ in. wide. From the occurrence of such specimens so near each other, Dr. Abbott thinks that we must admit that the antiquity of American man is greater than the advent of the so-called "Indian."

The Royal Geographical Society have awarded the following medals for the present year:—In Physical Geography: Gold medal to W. C. Hudson, age 18, of Liverpool College; bronze medal to W. A. Forbes, age 17, of Winchester College. In Political Geography: Gold medal to S. E. Spring Rice, age 16, of Eton College; bronze medal to A. T. Nutt, age —, of University College School.

At the meeting of the Royal Geographical Society on Monday, Sir Henry Rawlinson said despatches with reference to the East Coast Livingstone Expedition had been received from Sir Bartle Frere, dated March 27. The English portion of the expedition had been recently materially augmented, for, instead of consisting as previously of Lieut. Cameron and Dr. Dillan, it had received the valuable services of Lieut. Murphy, an officer of Engineers, who had obtained permission from the Indian Government to join it. Mr. Moffatt, a nephew of Dr. Livingstone, had also joined the expedition, and there was every reason to expect that his assistance would be of the greatest use in time of need. Bergamoyo had been already reached, and by the latest accounts the march into the interior had been commenced. From the first camp, at a distance of twenty miles from Bergamoyo, communications had been received from Dr. Dillan, in which he intimated his expectation of being speedily joined by Lieut. Cameron, Lieut. Murphy, and Dr. Moffatt. They would, notwithstanding the fact that the rainy season was not yet over, at once proceed on their journey.

Prof. Thiselton Dyer announces a course of six lectures on the "Aspects of Vegetation" at the Royal Horticultural Society's Gardens; and Mr. Thomas Moore a course of six demonstrations on "Medical Botany" in the Chelsea Botanic Garden.

A twice-monthly scientific periodical, in Turkish, is to be brought out in Constantinople called the *Dolab*, the *Repository*.

On Jan. 31 there was a slight shock of earthquake at Rangoon in English Burmah. On Feb. 12 an earthquake was felt at Peshawur and Lahore in India. Slight earthquake shocks were felt on March 14, at 8 p.m., at Yanina (Janina) in Albania, Turkey.

There is a report from Doncaster to the effect that shortly after two o'clock on Tuesday afternoon the town was visited by a smart shock of earthquake, which shook several houses to their foundations. In our correspondence this week will be found an account of an earthquake which occurred recently in the south of Scotland.

The French Association for the Advancement of Science, commences its second annual session at Lyons on August 21. We believe that there is every hope of a most numerous and interesting meeting.

The *New York Journal of Applied Chemistry* for February contains a very excellent article on "The Promotion of Scientific Research," by Prof. C. A. Joy, in which he animadverts severely on those so-called "practical men" who test the value of all scientific investigation by the "What is the use?" standard. "Original research," the writer says, "is the nervous fluid that furnishes strength to the muscle. The brawny arm is but dead meat unless the body is fed with nourishing food. Theodore Parker, in one of his discourses, alludes to the figure of a Chinaman in a shop window turning vigorously a crank; upon investigation he found that it was the crank that turned the man, and not the man the crank. It is the same with practical applications. The practical man applies the principle, and with great pomp and arrogance claims to turn the crank; it is not true—a power higher than his is behind it all; the original investigation, the discovery of the principle upon which the movement rests, is really the engine that drives the man and makes him do its bidding." Prof. Joy in speaking of the recent article in Nature, in which Sir Benjamin Brodie calls attention to the enormous expenditure of money of the University of Oxford, in the way of subsidies to students and annuities to fellows, without any adequate results, counsels the Americans to forbear copying the English University system. He proposes the following plan of promoting scientific research:—Let there be incorporated a society for the promotion of scientific research, to consist of a small number of strictly scientific trustees, who shall hold the property and appropriate the income to such objects as they deem worthy of aid. It would not be, strictly speaking, a society, but a foundation for the purposes specified. The head-quarters of the corporation should be in New York City. If the wealthy citizens of New York, who owe all they possess to the progress of science, would give money into the hands of such a board of trustees, they would be doing a most important work. Wherever and whenever any person was known to be engaged in the prosecution of some scientific research, the trustees could make him an allowance for conducting the inquiry, or to enable him to publish his results. Such assistance would often secure important discoveries. There are numerous professors scattered over the country whose salary is so small that they are obliged to add to it by outside work, or whose services at the college are so pressing that they have no leisure for anything like voluntary labour. A little assistance and encouragement to such persons would go a great way. Any college would be flattered by having their officers thus singled out by the best judges of the country as worthy of a subsidy from a society founded to encourage research. This course is preferable to giving a fund to a college for educational purposes, or to found a professorship, as the means for education are very great in this country, and there is far less need of mere educational facilities than there is of men engaged in purely scientific study. It has often happened that money has been raised to found a professorship for a particularly able man; after his death a person of inferior ability takes his place, and thus the object of the donor is defeated. It is therefore better to put the money into the hands of trustees selected for the purpose, and let them pay the income to those who are known to be worthy to receive it. The demands upon the fortunes of our wealthy men are constant and numerous, and they naturally give to such objects as are within their comprehension. If they could be made to understand that the source of our prosperity is science, and that the springs of discovery whence flow all the improvements of the day must be kept perennial, they would freely give of their substance, and we should soon see the watch-fires of original research kindled over the whole country.

The New York Nautical School-ship *Mercury* has spent the past winter in deep-sea research, as in a previous season, and,

as before, has utilised the opportunities presented in the interest of science. Captain Giraud surveyed a large portion of the so-called "volcanic region" of the Atlantic Ocean, finding the water very deep in that vicinity. Specimens brought up from the bottom appeared to be of undoubted volcanic origin. The Casella-Miller deep-sea thermometer was used on one occasion at a depth of 2,040 fathoms, two miles north of the equator, in longitude 22° 16′ west, and indicated a temperature of 35° F., at 1,000 fathoms 38°, and at the surface 81°, the air being 80°. During the voyage from the Canary Islands to Rio the temperature at uniform depths was found to vary only about two degrees.

THE Iron-Steel Institute conclude their meeting at Willis's Rooms to-day.

PRIZES for papers on the "Elvan Courses" of Cornwall, are offered by Mr. J. A. Phillips, F.C.S., to the present and former pupils of the Miners' Association of Cornwall and Devon. The papers and illustrative specimens are to be deposited with Mr. J. H. Collins, F.G.S., Hon. Assistant Secretary of the Miners' Association, Polytechnic Hall, Falmouth, on or before Sept. 1, 1873. The author of the best paper will be entitled to a prize (in books, selected by himself) of the value of 5*l*. A second prize, also in books, of the value of 3*l*., will be given to the author of the paper next in order of merit.

WE have received the first number of a new American journal, started last month, *The Sanitarian*, edited by Dr. A. N. Bell, of New York. It aims at presenting the results of the various inquiries which have been, and which hereafter may be made, for the preservation of health and the expectations of human life, so as to make them most advantageous to the public and to the medical profession. Among the most important articles is one by the editor, on "The New York Quarantine Establishment," which is illustrated with two maps. This is preceded by one on "Infant Mortality, with suggestions for improving the condition of Foundlings;" and followed by another on "The necessity of Re-Vaccination." We strongly recommend this excellently conducted journal to those interested in sanitary science.

AMONG the rarer and more interesting remains found in the mounds of the west of America, are plates of mica cut into different shapes, and evidently preserved as objects of great rarity and value; and, in the absence of this mineral in the Mississippi Valley, the question has frequently arisen whence the material could have been derived. A recent communication from Prof. W. C. Kerr, the State Geologist of North Carolina, tends to throw some light on this subject, and to open an interesting chapter in regard to the American prehistoric man. The work of collecting mica is at present carried on upon the largest scale in the high and rugged region between the Black Mountain, the Roanoke, and the head waters of the Nolachuchy, principally in Mitchell County, North Carolina. The region in question has long been known for the existence of numerous open works and tunnels, which, at first sight, were supposed to have been made in the search for silver or some other valuable metal. Prof. Kerr, in his capacity of State Geologist, was led to investigate this question, and very soon found, in every instance, that the excavations referred to were much older than the earliest discovery of the country by the Spaniards, and that in all cases they were found in ledges of coarse granite, which contained nothing but large patches of mica. Prof. Kerr has been satisfied for some time that in these mines we have the work of the contemporaries of the mound-builders, and the localities whence they derived the mica. What use they made of it we cannot say; but it is suggested that it may have served the purpose of mirrors, or possibly have been used as windows, as well as for ornament. The number and size of these mines is remarkable, some of the open cuts being more than 100 ft. in diameter, and 20 ft. or 30 ft. in depth, even after the caving in and filling up of centuries of weathering. The tunnels often extend inwards several yards, but are said to be too small for a man of ordinary size to work in. These show distinct marks of the tool in the granitic wall, as if made by a chisel-shaped instrument about an inch broad. Numerous plates of mica are found in these tunnels and excavations, some of them trimmed to particular shapes. These facts open up a new chapter in the history of the American aborigines, illustrating the character of the commerce carried on at a very remote period, and showing the magnitude of the operations, and the extended period of time over which they must have been prosecuted, to enable a people furnished with nothing better than wooden and stone tools to produce excavations of so great magnitude.

Sirius, a journal of popular astronomy published at Leipzig and Vienna, contains, in its fourth number for this year, a lecture by Prof. Oppolzer, on "The Importance of Astronomy in connection with Ancient History," the continuation of an article on "Copernicus and his Anniversary," one of a series of articles on the "Topography of the Heavens," the present treating of the constellation Gemini, besides a few notes.

THE additions to the Zoological Society's Gardens during the last week include a Ring-necked Parakeet (*Palæornis torquata*) from India, presented by Mr. W. E. Johnson; a long-eared Owl (*Otus vulgaris*) from Europe, presented by Dr. Bree; a Wood Owl (*Syrnium aluco*), presented by Mr. H. W. L. Browne; a Chinese Harrier (*Circus spilonotus*); a grey Eagle Owl (*Bubo cinereus*) and a Bosman's Potto (*Perodicticus potto*) from W. Africa; a horned Tragopan (*Ceriornis satyra*) from the Himalayas; a black-tailed Hawfinch (*Coccothraustes melanurus*) from Japan; two crested Buntings (*Melophus melanicterus*); two red-eared Bulbuls (*Pycnonotus jocosus*), and a red-vented Bulbul (*P. hæmorrhous*) from India; a red-headed Bunting (*Emberiza rutila*), and a yellow-browed Bunting (*E. chrysophrys*) from Japan; a black Tanager (*Tachyphonus melaleucus*) from S. America, purchased; two Emus (*Dromæus novæ-hollandiæ*) from Australia, deposited; a great Kangaroo (*Macropus giganteus*), and a Derbian Wallaby (*Halmaturus derbianus*), born in the gardens.

ON THE HYPOTHESES WHICH LIE AT THE BASES OF GEOMETRY*

Plan of the Investigation

IT is known that geometry assumes, as things given, both the notion of space and the first principles of constructions in space. She gives definitions of them which are merely nominal, while the true determinations appear in the form of axioms. The relation of these assumptions remains consequently in darkness; we neither perceive whether and how far their connection is necessary, nor, *a priori*, whether it is possible.

From Euclid to Legendre (to name the most famous of modern reforming geometers) this darkness was cleared up neither by mathematicians nor by such philosophers as concerned themselves with it. The reason of this is doubtless that the general notion of multiply extended magnitudes (in which space-magnitudes are included) remained entirely unworked. I have in the first place, therefore, set myself the task of constructing the notion of a multiply extended magnitude out of general notions of magnitude. It will follow from this that a multiply extended magnitude is capable of different measure-relations, and consequently that space is only a particular case of a triply extended magnitude. But hence flows as a necessary consequence that the propositions of geometry cannot be derived from general notions of magnitude, but that the properties which distinguish space from other conceivable triply extended magnitudes are only to be

* By Bernhard Riemann. (Translated by Prof. W. K. Clifford, from vol. xiii. of the Göttingen Abhandlungen.)

deduced from experience. Thus arises the problem, to discover the simplest matters of fact from which the measure-relations of space may be determined; a problem which from the nature of the case is not completely determinate, since there may be several systems of matters of fact which suffice to determine the measure-relations of space—the most important system for our present purpose being that which Euclid has laid down as a foundation. These matters of fact are—like all matters of fact—not necessary, but only of empirical certainty; they are hypotheses. We may therefore investigate their probability, which within the limits of observation is of course very great, and inquire about the justice of their extension beyond the limits of observation, on the side both of the infinitely great and of the infinitely small.

I.—*Notion of an* n*-ply extended magnitude*

In proceeding to attempt the solution of the first of these problems, the development of the notion of a multiply extended magnitude, I think I may the more claim indulgent criticism in that I am not practised in such undertakings of a philosophical nature where the difficulty lies more in the notions themselves than in the construction; and that besides some very short hints on the matter given by Privy Councillor Gauss in his second memoir on Biquadratic Residues, in the "Göttingen Gelehrte Anzeige," and in his Jubilee-book, and some philosophical researches of Herbart, I could make use of no previous labours.

§ 1.—Magnitude-notions are only possible where there is an antecedent general notion which admits of different specialisations. According as there exists among these specialisations a continuous path from one to another or not, they form a *continuous* or *discrete* manifoldness: the individual specialisations are called in the first case points, in the second case elements, of the manifoldness. Notions whose specialisations form a *discrete* manifoldness are so common that at least in the cultivated languages any things being given it is always possible to find a notion in which they are included. (Hence mathematicians might unhesitatingly found the theory of discrete magnitudes upon the postulate that certain given things are to be regarded as equivalent.) On the other hand, so few and far between are the occasions for forming notions whose specialisations make up a *continuous* manifoldness, that the only simple notions whose specialisations form a multiply extended manifoldness are the positions of perceived objects and colours. More frequent occasions for the creation and development of these notions occur first in the higher mathematic.

Definite portions of a manifoldness, distinguished by a mark or by a boundary, are called Quanta. Their comparison with regard to quantity is accomplished in the case of discrete magnitudes by counting, in the case of continuous magnitudes by measuring. Measure consists in the superposition of the magnitudes to be compared; it therefore requires a means of using one magnitude as the standard for another. In the absence of this two magnitudes can only be compared when one is a part of the other; in which case also we can only determine the more or less and not the how much. The researches which can in this case be instituted about them form a general division of the science of magnitude in which magnitudes are regarded not as existing independently of position and not as expressible in terms of a unit, but as regions in a manifoldness. Such researches have become a necessity for many parts of mathematics, *e.g.*, for the treatment of many-valued analytical functions; and the want of them is no doubt a chief cause why the celebrated theorem of Abel and the achievements of Lagrange, Pfaff, Jacobi for the general theory of differential equations, have so long remained unfruitful. Out of this general part of the science of extended magnitude in which nothing is assumed but what is contained in the notion of it, it will suffice for the present purpose to bring into prominence two points; the first of which relates to the construction of the notion of a multiply extended manifoldness, the second relates to the reduction of determinations of place in a given manifoldness to determinations of quantity, and will make clear the true character of an n-fold extent.

§ 2.—If in the case of a notion whose specialisations form a continuous manifoldness, one passes from a certain specialisation in a definite way to another, the specialisations passed over form a simply extended manifoldness, whose true character is that in it a continuous progress from a point is possible only on two sides, forwards or backwards. If one now supposes that this manifoldness in its turn passes over into another entirely different, and again in a definite way, namely so that each point passes over into a definite point of the other, then all the specialisations so obtained form a doubly extended manifoldness. In a similar manner one obtains a triply extended manifoldness, if one imagines a doubly extended one passing over in a definite way to another entirely different; and it is easy to see how this construction may be continued. If one regards the variable object instead of the determinable notion of it, this construction may be described as a composition of a variability of $n+1$ dimensions out of a variability of n dimensions and a variability of one dimension.

§ 3.—I shall now show how conversely one may resolve a variability whose region is given into a variability of one dimension and a variability of fewer dimensions. To this end let us suppose a variable piece of a manifoldness of one dimension—reckoned from a fixed origin, that the values of it may be comparable with one another—which has for every point of the given manifoldness a definite value, varying continuously with the point; or, in other words, let us take a continuous function of position within the given manifoldness, which, moreover, is not constant throughout any part of that manifoldness. Every system of points where the function has a constant value, forms then a continuous manifoldness of fewer dimensions than the given one. These manifoldnesses pass over continuously into one another as the function changes; we may therefore assume that out of one of them the others proceed, and speaking generally this may occur in such a way that each point passes over into a definite point of the other; the cases of exception (the study of which is important) may here be left unconsidered. Hereby the determination of position in the given manifoldness is reduced to a determination of quantity and to a determination of position in a manifoldness of less dimensions. It is now easy to show that this manifoldness has $n-1$ dimensions when the given manifoldness is n-ply extended. By repeating then this operation n times, the determination of position in an n-ply extended manifoldness is reduced to n determinations of quantity, and therefore the determination of position in a given manifoldness is reduced to a finite number of determinations of quantity *when this is possible*. There are manifoldnesses in which the determination of position requires not a finite number, but either an endless series or a continuous manifoldness of determinations of quantity. Such manifoldnesses are, for example, the possible determinations of a function for a given region, the possible shapes of a solid figure, &c.

II.—*Measure-relations of which a manifoldness of* n *dimensions is capable on the assumption that lines have a length independent of position, and consequently that every line may be measured by every other.*

Having constructed the notion of a manifoldness of n dimensions, and found that its true character consists in the property that the determination of position in it may be reduced to n determinations of magnitude, we come to the second of the problems proposed above, viz., the study of the measure-relations of which such a manifoldness is capable, and of the conditions which suffice to determine them. These measure-relations can only be studied in abstract notions of quantity, and their dependence on one another can only be represented by formulæ. On certain assumptions, however, they are decomposable into relations which, taken separately, are capable of geometric representation; and thus it becomes possible to express geometrically the calculated results. In this way, to come to solid ground, we cannot, it is true, avoid abstract considerations in our formulæ, but at least the results of calculation may subsequently be presented in a geometric form. The foundations of these two parts of the question are established in the celebrated memoir of Gauss—"Disquisitiones generales circa superficies curvas."

§ 1.—Measure-determinations require that quantity should be independent of position, which may happen in various ways. The hypothesis which first presents itself, and which I shall here develop, is that according to which the length of lines is independent of their position, and consequently every line is measurable by means of every other. Position-fixing being reduced to quantity-fixings, and the position of a point in the n-dimensioned manifoldness being consequently expressed by means of n variables $x_1, x_2, x_3, \ldots x_n$, the determination of a line comes to the giving of these quantities as functions of one variable. The problem consists then in establishing a mathematical expression for the length of a line, and to this end we must consider the quantities x as expressible in terms of certain units. I

shall treat this problem only under certain restrictions, and I shall confine myself in the first place to lines in which the ratios of the increments dx of the respective variables vary continuously. We may then conceive these lines broken up into elements, within which the ratios of the quantities dx may be regarded as constant; and the problem is then reduced to establishing for each point a general expression for the linear element ds starting from that point, an expression which will thus contain the quantities x and the quantities dx. I shall suppose, secondly, that the length of the linear element, to the first order, is unaltered when all the points of this element undergo the same infinitesimal displacement, which implies at the same time that if all the quantities dx are increased in the same ratio, the linear element will vary also in the same ratio. On these suppositions, the linear element may be any homogeneous function of the first degree of the quantities dx, which is unchanged when we change the signs of all the dx, and in which the arbitrary constants are continuous functions of the quantities x. To find the simplest cases, I shall seek first an expression for manifoldnesses of $n-1$ dimensions which are everywhere equidistant from the origin of the linear element; that is, I shall seek a continuous function of position whose values distinguish them from one another. In going outwards from the origin, this must either increase in all directions or decrease in all directions; I assume that it increases in all directions, and therefore has a minimum at that point. If, then, the first and second differential coefficients of this function are finite, its first differential must vanish, and the second differential cannot become negative; I assume that it is always positive. This differential expression, then, of the second order remains constant when ds remains constant, and increases in the duplicate ratio when the dx, and therefore also ds, increase in the same ratio; it must therefore be ds^2 multiplied by a constant, and consequently ds is the square root of an always positive integral homogeneous function of the second order of the quantities dx, in which the coefficients are continuous functions of the quantities x. For Space, when the position of points is expressed by rectilinear co-ordinates, $ds=\sqrt{\Sigma(dx)^2}$; Space is therefore included in this simplest case. The next case in simplicity includes those manifoldnesses in which the line-element may be expressed as the fourth root of a quartic differential expression. The investigation of this more general kind would require no really different principles, but would take considerable time and throw little new light on the theory of space, especially as the results cannot be geometrically expressed; I restrict myself, therefore, to those manifoldnesses in which the line-element is expressed as the square root of a quadric differential expression. Such an expression we can transform into another similar one if we substitute for the n independent variables functions of n new independent variables. In this way, however, we cannot transform any expression into any other; since the expression contains $n\frac{n+1}{2}$ coefficients which are arbitrary functions of the independent variables; now by the introduction of new variables we can only satisfy n conditions, and therefore make no more than n of the coefficients equal to given quantities. The remaining $n\frac{n-1}{2}$ are then entirely determined by the nature of the continuum to be represented, and consequently $n\frac{n-1}{2}$ functions of positions are required for the determination of its measure-relations. Manifoldnesses in which, as in the Plane and in Space, the line-element may be reduced to the form $\sqrt{\Sigma dx^2}$, are therefore only a particular case of the manifoldnesses to be here investigated; they require a special name, and therefore these manifoldnesses in which the square of the line-element may be expressed as the sum of the squares of complete differentials I will call *flat*. In order now to review the true varieties of all the continua which may be represented in the assumed form, it is necessary to get rid of difficulties arising from the mode of representation, which is accomplished by choosing the variables in accordance with a certain principle.

§. 2.—For this purpose let us imagine that from any given point the system of shortest lines going out from it is constructed; the position of an arbitrary point may then be determined by the initial direction of the geodesic in which it lies, and by its distance measured along that line from the origin. It can therefore be expressed in terms of the ratios dx_0 of the quantities dx in this geodesic, and of the length s of this line. Let us introduce now instead of the dx_0 linear functions dx of them, such that the initial value of the square of the line-element shall equal the sum of the squares of these expressions, so that the independent variables are now the length s and the ratios of the quantities dx. Lastly, take instead of the dx quantities $x_1 x_2 x_3 \ldots x_n$ proportional to them, but such that the sum of their squares $= s^2$. When we introduce these quantities, the square of the line-element is Σdx^2 for infinitesimal values of the x, but the term of next order in it is equal to a homogeneous function of the second order of the $n\frac{n-1}{2}$ quantities $(x_1\,dx_2 - x_2\,dx_1)$, $(x_1\,dx_3 - x_3\,dx_1)\ldots$ an infinitesimal, therefore, of the fourth order; so that we obtain a finite quantity on dividing this by the square of the infinitesimal triangle, whose vertices are $(0, 0, 0, \ldots)$, $(x_1 x_2 x_3 \ldots)$, $(dx_1, dx_2, dx_3, \ldots)$. This quantity retains the same value so long as the x and the dx are included in the same binary linear form, or so long as the two geodesics from 0 to x and from 0 to dx remain in the same surface-element; it depends therefore only on place and direction. It is obviously zero when the manifold represented is flat, *i.e.* when the squared line-element is reducible to Σdx^2, and may therefore be regarded as the measure of the deviation of the manifoldness from flatness at the given point in the given surface-direction. Multiplied by $-\frac{3}{4}$ it becomes equal to the quantity which Privy-councillor Gauss has called the total curvature of a surface. For the determination of the measure-relations of a manifoldness capable of representation in the assumed form we found that $n\frac{n-1}{2}$ place-functions were necessary; if, therefore, the curvature at each point in $n\frac{n-1}{2}$ surface-directions is given, the measure-relations of the continuum may be determined from them—provided there be no identical relations among these values, which in fact, to speak generally, is not the case. In this way the measure-relations of a manifoldness in which the line-element is the square root of a quadric differential may be expressed in a manner wholly independent of the choice of independent variables. A method entirely similar may for this purpose be applied also to the manifoldness in which the line element has a less simple expression, *e.g.*, the fourth root of a quartic differential. In this case the line-element, generally speaking, is no longer reducible to the form of the square root of a sum of squares, and therefore the deviation from flatness in the squared line-element is an infinitesimal of the second order, while in those manifoldnesses it was of the fourth order. This property of the last-named continua may thus be called flatness of the smallest parts. The most important property of these continua for our present purpose, for whose sake alone they are here investigated, is that the relations of the twofold ones may be geometrically represented by surfaces, and of the morefold ones may be reduced to those of the surfaces included in them; which now requires a short further discussion.

§ 3.—In the idea of surfaces, together with the intrinsic measure-relations in which only the length of lines on the surfaces is considered, there is always mixed up the position of points lying out of the surface. We may, however, abstract from external relations if we consider such deformations as leave unaltered the length of lines—*i.e.* if we regard the surface as bent in any way without stretching, and treat all surfaces so related to each other as equivalent. Thus, for example, any cylindric or conical surface counts as equivalent to a plane, since it may be made out of one by mere bending, in which the intrinsic measure-relations remain, and all theorems about a plane—therefore the whole of planimetry—retain their validity. On the other hand they count as essentially different from the sphere, which cannot be changed into a plane without stretching. According to our previous investigation the intrinsic measure-relations of a twofold extent in which the line-element may be expressed as the square root of a quadric differential, which is the case with surfaces, are characterised by the total curvature. Now this quantity in the case of surfaces is capable of a visible interpretation, viz, it is the product of the two curvatures of the surface, or multiplied by the area of a small geodesic triangle, it is equal to the spherical excess of the same. The first definition assumes the proposition that the product of the two radii of curvature is unaltered by mere bending; the second, that in the same place the area of a small triangle is proportional to its spherical excess. To give an intelligible meaning to the curvature of an n-fold extent at a given point and in a given surface-direction through it, we must start from the fact that a geodesic proceeding

from a point is entirely determined when its initial direction is given. According to this we obtain a determinate surface if we prolong all the geodesics proceeding from the given point and lying initially in the given surface-direction; this surface has at the given point a definite curvature, which is also the curvature of the n-fold continuum at the given point in the given surface-direction.

§ 4.—Before we make the application to space, some considerations about flat manifoldnesses in general are necessary; *i.e.* about those in which the square of the line-element is expressible as a sum of squares of complete differentials.

In a flat n-fold extent the total curvature is zero at all points in every direction; it is sufficient, however (according to the preceding investigation), for the determination of measure-relations, to know that at each point the curvature is zero in $n\frac{n-1}{2}$ independent surface directions. Manifoldnesses whose curvature is constantly zero may be treated as a special case of those whose curvature is constant. The common character of these continua whose curvature is constant may be also expressed thus, that figures may be moved in them without stretching. For clearly figures could not be arbitrarily shifted and turned round in them if the curvature at each point were not the same in all directions. On the other hand, however, the measure-relations of the manifoldness are entirely determined by the curvature; they are therefore exactly the same in all directions at one point as at another, and consequently the same constructions can be made from it: whence it follows that in aggregates with constant curvature figures may have any arbitrary position given them. The measure-relations of these manifoldnesses depend only on the value of the curvature, and in relation to the analytic expression it may be remarked that if this value is denoted by α, the expression for the line-element may be written

$$\frac{1}{1+\frac{\alpha}{4}\Sigma x^2}\sqrt{\Sigma dx^2}$$

§ 5.—The theory of *surfaces* of constant curvature will serve for a geometric illustration. It is easy to see that surfaces whose curvature is positive may always be rolled on a sphere whose radius is unity divided by the square root of the curvature; but to review the entire manifoldness of these surfaces, let one of them have the form of a sphere and the rest the form of surfaces of revolution touching it at the equator. The surfaces with greater curvature than this sphere will then touch the sphere internally, and take a form like the outer portion (from the axis) of the surface of a ring; they may be rolled upon zones of spheres having less radii, but will go round more than once. The surfaces with less positive curvature are obtained from spheres of larger radii, by cutting out the lune bounded by two great half-circles and bringing the section-lines together. The surface with curvature zero will be a cylinder standing on the equator; the surfaces with negative curvature will touch the cylinder externally and be formed like the inner portion (towards the axis) of the surface of a ring. If we regard these surfaces as *locus in quo* for surface-regions moving in them, as Space is *locus in quo* for bodies, the surface regions can be moved in all these surfaces without stretching. The surfaces with positive curvature can always be so formed that surface regions may also be moved arbitrarily about upon them without *bending*, namely (they may be formed) into sphere-surfaces; but not those with negative curvature. Besides this independence of surface regions from position there is in surfaces of zero curvature also an independence of *direction* from position, which in the former surfaces does not exist.

(*To be continued.*)

SCIENTIFIC SERIALS

Zeitschrift für Ethnologie, No. 6.—The present number gives a compendium of useful suggestions, which might advantageously be acted on in other countries besides Germany, addressed by the Anthropological Society of Berlin to all persons engaged in exploring, or other expeditions to distant regions. In those directions for observing and collecting whatever is most adapted to extend and rectify our actual knowledge, information is given in regard to the various races with whom travellers may come in contact, and the special geographical, linguistic, social and other conditions, which more particularly require further elucidation. —Prof. A. Bastian gives us in this number with his habitual completeness an exposition of the worship of the heavenly bodies among different nations, and the extent to which local conditions of climate and ethnological differences have influenced the character of the adoration offered to the sun and the moon and the stars. According to him a *true* worship of the sun—except in the polar regions—is only to be found on elevated plateaux, where the return of the orb of day was welcomed with gratitude after the colder night, while in low-lying tropical lands the aborigines looked with dread at the glowing ball of fire which each summer seemed to threaten their world with annihilation. We can strongly commend this paper as a most comprehensive, although not specially novel exposition of Aryan and other mythological systems.—The German engineer, Herr H. Keplin, has drawn attention to the mussel-hills (*Casqueiros sambaquis*) of Brazil in the district of the Rio do San Francisco do Sol. The position of these deposits appears to refute the idea of their being mere Kjokkenmödings, while the great respect shown by the natives for the dead, and their care to provide them proper sepulture, would seem to afford further evidence that these elevations, which often rise to a height of 50 feet, cannot be due to the hand of man. In reference to the above, it may interest our own archæologists to know that Herr Walter Kauffman draws attention in the same number to his discovery in the neighbourhood of Hull, at a spot known as Castle Hill, near Holderness, of a burial place belonging, as he conjectures, to the transition period between the Stone and Bronze ages. Herr Kauffman found on the western side of the hill, where the ground had been cut for building purposes, a fragment of some loam vessel, a compact mass of oyster shells, some flint flakes, and a human rib. After carefully removing the earth, Herr K. discovered at from 4 to 4½ feet below the surface the vertebræ of another skeleton, and finally collected nearly all the bones of two skeletons, completely enclosed in a mass of oyster shells.—Dr. A. B. Meyer, of Manilla, in the course of a short visit in the Philippines, found skulls which presented that peculiar appearance of sharpening or filing of the teeth, described by the old traveller, Thévenot, and the accuracy of which has often been called in question. The Negrito skulls from the Philippines, examined by Dr. Meyer, also exhibited the artificial flattening of the heads noticed by Thévenot.—Herr Virchow drew attention last summer to the fact that occasional deviations present themselves from the normal cranial configuration of a race, which ought to teach us extreme caution in regarding any single specimen as a typical form. He was led to make this remark by his observation in the Anatomical Museum of Copenhagen of the skull of Kay Lykke, a man of the noblest Danish descent, who had flourished two hundred years ago, and been celebrated in his day for his personal beauty, his effeminacy, and the sensual bias of his disposition. Yet the skull of this once elegant, accomplished, and self-indulgent courtier of the 17th century, belonging to an otherwise brachycephalic race, is more strikingly dolichocephalic and depressed than the Neanderthal head, and might readily be supposed to have belonged to an Australian savage. The cranial capacity which is given by Professor Panum, of Copenhagen, as 1,250 cubic centrm., is, moreover, below the amount that is conjecturally assumed for the Neanderthal skull.

The supplement to the vol. of the "Zeits. f. Ethnologie," for 1872, is exclusively occupied with the Linguistic Notes of Dr. G. Schweinfurth, drawn up as the result of his travel in Central Africa, and gives numerous vocabularies and specimens of the languages of the different tribes who occupy the district of the Bahr-el-Ghasal, among whom Dr. Schweinfurth lived more than two years.

Nuovo Giornale Botanico Italiano, vol. iv. Nos. 1—4, Jan.—Dec., 1872. The volume for 1872 of this journal, edited by one of the most accomplished of Italian botanists, Prof. Caruel, contains evidence of considerable scientific activity in the Peninsula. A large space of these four numbers is devoted to cryptogamic botany; we have papers on the mosses of Abyssinia, by De Venturi, and of Ceylon and Borneo, by Hampe; on the fungi of Parma, by Passerini; on Diatoms, by Ardissone, and on a new classification of cryptogams, proposed by Prof. Cohn. Besides several papers on systematic, descriptive, and geographical botany, one of the most interesting on physiological and histological subjects is by Saccardo, on the amyloid corpuscles contained within the fovilla of pollen, illustrated by a plate. Prof. Caruel contributes a very valuable biographical notice of the Italian botanist, Andrea Cesalpino, born at Arezzo in 1519, and a summary of the contents of his great

work, "De Plantis," published at Florence in 1583, which his biographer states to contain the essential features of the classification propounded by A. L. Jussieu two centuries later.

Annalen der Chemie und Pharmacie, February, 1873. The number commences with a paper on a new derivative of sulphocarbamic acid, by H. Hlasiwetz and J. Kachler. The new body is obtained by the action of carbonic disulphide on camphor in the presence of ammonia. Measurements of its crystals are given. The numbers obtained by an analysis agree well with the formula C_2, H_{10}, N_4, S_2; this is regarded as an ammonia salt; a copper compound C_2, H_2, N_2, S_3, Cu, has been obtained, but the acid cannot be isolated from it, as SH_2 refuses to precipitate the copper. Several other compounds of the body are described.—The next paper is a short note by M. Berthelot on the formation of Acetylen by the silent electric discharge. Messrs. R. Boettger and Theodor Petersen contribute a paper on the Nitro-compounds of Anthrachinon. The following bodies are described: α Mononitroanthrachinon, α Monamidoanthrachinon, and α Diazoanthrachinon Nitrate; the behaviour of these α bodies with concentrated sulphuric acid is then described.—On the Vanadates of Thallium, by Thomas Carnelly. The author describes the method of preparation and properties of the salts in question; this paper has already appeared in the April number of the Chemical Society's journal, as also has the next, on Ethyl-amyl, by Harry Grimshaw, and Schorlemmer's paper on the Heptanes from Petroleum.—Crystallographic Notices, I. by C. Klein, is a long paper on the measurement, &c. of crystals; a contribution to our knowledge of Neurin, by Julius Mauthner; "Remarks on my Water Air-pump," by N. Jagn; and a paper on Excretin from Human Excrement, by F. Hinterberger. The author has established the formula C_{20}, $H_{36}O$ for this body, and has obtained a Brominated derivative C_{20}, H_{34}, $Br._2$ O.

Bulletin de la Société de Géographie.—The first article in the March number is by the Abbé Durand, formerly a missionary in Brazil, on the Solimoes, the name given to the Amazon from its junction with the Rio Negro upwards, this being the name of the most powerful tribe on its banks. The Abbé gives an account of his journey up the river as far as Peru. His article contains many valuable facts as to towns, and people, and products of the district through which he passed. The next article is the last of Capt. Derrégagaix's papers on the South of the Province of Oran; the present one treating of the Geology and Meteorology of the district. This is followed by a translation of part of Col. Yule's essay on the geography of the Oxus prefixed to Wood's "Journey to the Source of the Oxus."—M. N. de Khanikoff contributes a paper on our knowledge of the Khanate of Khiva.

SOCIETIES AND ACADEMIES

London

Royal Society, April 24.—On the Durability and Preservation of Iron Ships, and on Riveted Joints, by Sir William Fairbairn, Bart., F.R.S.

On the employment of Meteorological Statistics in determining the best course for a Ship whose sailing qualities are known, by Francis Galton, F.R.S.

Zoological Society, April 29.—Anniversary Meeting.—Viscount Walden, F.R.S., president, in the chair.—After some preliminary business the report of the Council was read by the Secretary, Mr. P. L. Sclater, F.R.S. It stated that the number of ordinary members of the Society on January 1 last, was 3,050, of Foreign members, 25, and of Corresponding members, 197. The total income of the Society in 1872 was 26,728*l*., being 2,017*l*. more than that of 1871, and exceeding the income of any previous year, except that of the year 1862, when the International Exhibition was held. The total expenditure of 1872 had been 26,900*l*., and a balance of 1,956*l*. had been carried forward for the benefit of the current year. The assets of the Society on December 31, 1872, were calculated at 10,532*l*., while the liabilities were reckoned at 5,490*l*. The Reserve-fund consisted of a sum of 8,000*l*. Reduced 3 per Cents. The Scientific publications of the Society for 1872 had consisted of the usual volume of "Proceedings," four parts of "Transactions," a Revised List of the Vertebrated Animals, now or lately living in the Society's Gardens, and a General Index to the ten years of the Society's "Proceedings," from 1861 to 1870. The most important work undertaken in the Society's Gardens in 1872 had been the bridge over the Regent's Park Canal, intended to connect the Society's new grounds on the north bank, with the present Gardens. This had been completed in October last at a total cost of 1,333*l*. The new Lodge and Entrance-gates in Primrose-hill Road had likewise been finished, and the new entrance opened to the public for the first time on Easter Monday. The total number of visitors to the Society's Gardens in 1872 had been 648,088 being 52,171 more than the corresponding number in 1871. The greatest number of admissions in any one day in 1872 had been 44,608, which took place on May 20 (Whit Monday). The number of animals in the Menagerie on Dec. 31, 1872, was 2,010. Many of the accessions during the year had consisted of specimens of rare or little known animals, of which full particulars are given. The Report concluded with a long list of donors, and their several donations to the Menagerie. The Meeting then proceeded to elect the new Members of Council and the Officers for the ensuing year, and a ballot having been taken it was found that Viscount Walden, F.R.S., had been elected President, Mr. Robert Drummond, Treasurer, and Mr. P. L. Sclater, F.R.S., Secretary of the Society. The new Members of Council elected were Francis Galton, F.R.S., John P. Gassiott, Jun., St. George Mivart, F.R.S., George Russell, and Richard H. S. Vyvyan.

Geological Society, April 9.—His Grace the Duke of Argyll, K.T., F.R.S., president, in the chair. The following communications were read:—"Lakes of the north-eastern Alps, and their bearing on the Glacier-erosion Theory," by the Rev. T. G. Bonney, F.G.S. The purpose of this paper was to test, by the lakes of the Salzkammergut and neighbourhood, the theory of the erosion of lake-basins by glaciers, which has been advanced by Prof. Ramsay. The author premised (1) that an extensive glacier could not exist without a considerable area to support it; (2) that under no circumstances could a glacier excavate a cliff of considerable height (say 1,000 ft.) approximately vertical; (3) that owing to the proximity of the regions, a theory of excavation which applied to the Western and Central Alps ought to be applicable also to the Eastern Alps. He then proceeded to examine a number of lakes in detail. The Königsee lies in a remarkably deep, steep-sided valley, terminated by a cirque, with cliffs full a thousand feet high, and has no large supply area behind. The Hallstadtersee is similarly situated, has a cirque at the head, and two lateral valleys nearly at right angles to the lake, up which arms of it have formerly extended. These are not likely to have furnished glaciers which could have excavated the lake; and above the cirque there is no large supply area. The Gasauthal consists of lake-basins separated by valleys of river-erosion. The Fuschelsee and Wolfgangersee, on the south side of the Schafberg, are separated by a narrow sharp ridge of hills, incapable of nourishing glaciers large enough to grind them out; there are no signs of glaciers from other directions having eroded them. The Mondsee and Attersee (once one lake) on the north lie under the steep cliffs of the Schafberg, which could not have nourished a large glacier; and the ridge of the Schafberg is too sharp to admit of the supposition that a great glacier, coming from the south, has passed over it to excavate the lake; yet the Attersee, in a position least favourable to glacial action, is the largest and deepest lake in the Salzkammergut. The head of the valley in which these lakes lie is really among low hills, in the direction of the Austro-Bavarian plain. The Traunsee was shown to give no evidence in favour of a theory of glacial erosion. Since then these lakes either had at their heads preglacial cirques (the very existence of which was incompatible with much erosive power on the part of a glacier), or were beneath sharp and not greatly elevated ridges of rock, the author concluded that they had not been excavated primarily by glaciers. He considered a far more probable explanation to be, that the greater lake-basins were parts of ordinary valleys, excavated by rain and rivers, the beds of which had undergone disturbances after the valley had assumed approximately its present contour. He showed that the lakes were in most cases maintained at their present level by drift; and that, while in a region so subject to slight disturbances as the Alps, positive evidence for his theory would be almost impossible to obtain, no lake offered any against it, and one, the Königsee, was very favourable to it.—"On the Effects of Glacier-erosion in Alpine Valleys," by Signor B. Gastaldi. The author described the occurrence in the valley of the Lanzo and other Alpine valleys, at heights between 2,000 and 3,000 metres (6,700 and 10,000 feet), of large cirques, in two of which, in the valley Sauze de Césanne, the bottom was occupied in the autumn

by glaciers reduced to their smallest dimensions. The author noticed the various rocks in which these cirques were cut, and expressed his opinion that they are the beds formerly occupied by glaciers, the power of which to excavate even comparatively hard rocks, such as felspathic, amphibolite, and chlorite-schists, he considered to be proved. The author then referred to the mouths of the Alpine valleys opening upon the plain, which he described as being generally very narrow in proportion to their length, width, and orographical importance; and he pointed out that in the case of the valley of the Stura, at any rate, the outlet of the valley has been cut out by the river. This peculiarity he accounts for by the fact that whilst the calcareous and felspathic rocks are easily disintegrated by atmospheric action, certain other rocks, such as the amphibolites, diorites, syenites, amphibolite-schists, euphotides, serpentines, &c., resist atmospheric denudation; and he indicated the peculiar distribution of these rocks in the region under consideration, by reason of which portions of them occupied the points which are now the mouths of the valleys.

Anthropological Institute, April 22.—Prof. Busk, F.R.S., president, in the chair.—The following papers were read:—The Religious Beliefs of the Ojibois or Santeux Indians resident in Manitoba and at Lake Winnepeg, by A. P. Reid, M.D.—The predominating Danish aspect of the local nomenclature of Cleveland, by Rev. J. C. Atkinson.—Rock Inscriptions in Brazil, by John Whitfield.—Remarks about the consecration of the Serpent as an Emblem but not an Object of Worship among the Intelligent Druids, by James Hutchiogs.

Entomological Society, April 7.—Prof. Westwood, president, in the chair.—Mr. Champion exhibited specimens of *Tribolium confusum* and *Ptinus testaceus*, which he had observed in British collections mistaken for *T. testaceum* and *P. fur*.—Mr. Verrall exhibited several new species of *Diptera* belonging to the families *Asilidæ* and *Syrphidæ*, taken in Britain.—Mr. McLachlan stated that he had been informed by Lord Walsingham that he had observed Dragon flies in California and Texas preyed upon by other large insects which seized them whilst flying through the air. The latter were, no doubt, some species of *Asilus*; but it was the first time he had heard of Dragon flies being preyed upon by other insects, as they had, hitherto, been supposed to be free from such attacks.—Mr. F. Smith made some remarks on a species of *Pentatoma* sent from Calcutta by Mr. Rothney, which was of the same colour as the bark of the tree on which it was observed in great numbers.—Major Parry communicated a paper on the characters of seven nondescript Lucanoid Coleoptera, with remarks on the genera *Lissotes*, *Nigidius*, and *Figulus*.—Mr. Frederick Bates communicated "Descriptions of new Genera and species of *Tenebrionidæ* from Australia, New Caledonia, and Norfolk Island."—Mr. Müller read some interesting remarks on the habits of the *Cynipidæ*, communicated to him in a letter from Mr. W. F. Bassett, of Waterburg, U.S.—Part I. of the Transactions for 1873 was on the table.

Meteorological Society, April 16.—Dr. Tripe, president, in the chair.—A discussion took place on the following questions which had been submitted to the consideration of the Meteorological Conference held at Leipzig in August last:—No. 2. Barometers for Stations of the second order. No. 4. Maximum and Minimum Thermometers. No. 5. Instruments for determining Solar Radiation. No. 18. Uniformity in Hours of Observation. No. 20. Division of the Year for the Calculation of Mean Results. On question No. 2, several spoke in favour of aneroids, and several that they were not to be trusted; the opinion of the meeting was that for hard rough work where the aneroid is exposed to low and high pressure it is not suited for taking correct observations, and that the Kew barometer is much to be preferred. On question No. 4 the testimony of the meeting was in favour of Phillips' and Negretti's maximum thermometer. On question 5, reference was made to a paper by Rev. F. W. Stow, M.A., on "Solar Radiation," which is printed in the Journal of the Society for April 1873. Time would not allow of questions 18 and 20 being fully discussed, so they will be brought up again at the meeting on May 21.

MANCHESTER

Literary and Philosophical Society, April 15.—R. Angus Smith, F.R.S., vice-president, in the chair.—Mr. Francis Nicholson exhibited two fine eggs of the golden eagle (*Falco chrysaëtos*) taken the previous week from a nest in the north of Scotland. Fortunately some of the large landed proprietors both in Scotland and Ireland are now preserving this noble bird from persecution during the breeding time.—A letter was read from Mr. William Boyd Dawkins, F.R.S., who, as Secretary of the Committee of the British Association for carrying on the exploration of the Victoria Cave, felt obliged to notice the "Notes on Victoria Cave," by Mr. W. Brockbank, published in the Proceedings, March 10, 1873. Mr. Dawkins submitted that until the work of the Committee, to which the cave has been handed over by the kindness of the owner, be finished, and the observations, to which Mr. Brockbank has had no access, be recorded, his notes must of necessity be imperfect and liable to error. Mr. Dawkins then calls attention to two matters of fact, in which he shows Mr. Brockbank's statement to be entirely unfounded.—"On some Improvements in Electro-Magnetic Induction Machines," by Mr. Henry Wilde.

PHILADELPHIA

Academy of Natural Sciences, October 15.—Prof. Leidy directed attention to the collection of fossils, from the vicinity of Fort Bridger, Wyoming, presented by Dr. J. Van A. Carter, Dr. Joseph K. Corson, U.S.A., and himself. Some of the fossils were referred to a huge pachyderm with the name of *Uintatherium robustum*. [This subject has already been several times referred to in NATURE. See Mr. A. H. Garrod's letter last week]. Prof. Leidy further called attention to a multitude of chipped stones, which he had collected about ten miles north-east of Fort Bridger. Many of the fragments are broken in such a manner that it is difficult to be convinced that they are not of artificial origin. The materials of the splintered stones consist of jaspers, quartzites, some of the softer rocks of the tertiary strata, and less frequently of black flint identical in appearance with that of the English chalk.

December 3, 1872.—The president, Dr. Ruschenberger, in the chair.—Joseph Wilcox made remarks about some glacial scorings lately observed by him in St. Lawrence County, N. Y.

December 10, 1872.—The president, Dr. Ruschenberger, in the chair.—Jos. Wilcox made the following remarks:—Having lately visited many mineral localities in Canada, I desire to place them on record, as many of them are not mentioned either in the "Geological Report of Canada," or in Dana's "Mineralogy." At the falls of Ottawa River at Grand Calumet Island, black mica (phlogopite), pyroxene, hornblende, serpentine, tremolite. The following localities are all in the Province of Ontario:—At Arnprior, Calcite (dog tooth spar); near Packenham, Hornblende; in Bathurst, pyroxene, scapolite, sphene, apatite, peristerite; two miles south-west of Perth, bronze mica (phlogopite), having beautiful hexagonal marks on the cleavage planes; near Otty Lake, in North Elmsley, Apatite, pyroxene, black mica (biotite), zircon, red spinel—chondrolite; in Burgess, apatite, black mica (biotite); near Bob Lake, twenty miles north-west of Perth, the best crystals of apatite are found; near the St. Lawrence River, six miles south-west of Brockville, large octahedral crystals of iron pyrites, some of them four inches in diameter. All of these minerals are well crystallized, except the peristerite and chondrolite.—Prof. Leidy directed attention to some fossils recently received from Dr. J. Van A. Carter, of Fort Bridger, Wyoming. They were—*Palæosyops junior*, *Uintacyon edax*, *Uintacyon vorax*, and *Chamæleo pristinus*.—Remarks on silver ore from Colorado, by George A. König.

December 17, 1872.—Dr. J. L. LeConte in the chair.—Prof. Cope made some remarks on the Geology of Wyoming, especially with reference to the age of the coal series of Bitter Creek. He said that discovery of the Dinosaur *Agathaumas sylvestris* bad settled the question of age, concerning which there had been much difference of opinion, in favour of the view that they constitute an upper member of the Cretaceous series. It appeared to the speaker, that the explorations directed by Dr. Hayden during the past season had contributed largely to our knowledge, proving the existence of an interruption between the cretaceous and tertiary formations: less it is true than that which exists elsewhere, and similar to that insisted on by Clarence King's survey in the region of Bear River and the Wahsatch country.—Prof. Cope defined a genus of Saurodont Fishes from the Niobrara Cretaceous of Kansas, under the name of *Erisichthe*. He stated that it agreed with *Portheus* and *Ichthyodectes* in the absence of nutritious dental foramina on the inner face of the dentary bone, and especially with *Portheus* in the irregular sizes of the teeth.

January 7.—Dr. Ruschenberger, president, in the chair—E. Goldsmith described what he considers a new mineral which he names *Trautwinite*, after its first observer, Mr. J. C. Trautwine. The mineral has a green colour; the hardness is between 1 and 2, and it is micro-crystalline. The regular forms, which he saw, were short hexagonal pyramids, the infinite pyramid (prism), and triangular slender prisms, which may be one-sixth sections of the hexagonal prism. Under ordinary circumstances the mineral is dull, but when observed under power it appears vitreous. The streak is light green. The qualitative chemical examination indicated the oxides of chromium, iron, and magnesium.—Prof. Cope remarked, that, through the kindness of Prof. B. F. Mudge, he had an opportunity of examining additional specimens of the turtle from the cretaceous of Kansas, described by him in the Proceedings of the Academy, 1872, p. 129. The phalanges indicated a large flipper of the type of marine turtles. They are more flattened than in the *Propluridæ* so far as the latter are known, and are proportionally larger. The genus and species were named *Toxochelys latiremis*.

PARIS

Academy of Sciences, April 21.—M. de Quatrefages president, in the chair.—The following papers were read.—A final answer to M. Secchi, by M. Faye. M. Faye called attention to the fact that Father Secchi has accused him of insinuating that his drawings of the spots are not authentic, which insinuation also applies to the drawings of Carrington and Father Tacchini. This he showed was not the case, his statement that photographs, and not drawings, were required, being perfectly obvious as regards its signification. He then proceeded to answer Secchi's statements as to eruptions projecting the erupted matter towards a common centre, and asked how it was that these masses cooled during a passage which lasted often but a day or two, or even a few hours, could produce spots which lasted for months. He then answered several other objections, and called attention to Respighi's observations of the chromosphere, the earliest, as they are the best yet executed, as fully bearing out his theory.—On the condensation of Carbonic Oxide and Hydrogen, and of Nitrogen and Hydrogen, by the silent electric discharge, by MM. P. and A. Thenard. The authors had noticed that the protocarbide of hydrogen and carbonic anhydride, which, under the silent discharge condensed to a liquid, were doubled in volume and converted into carbonic oxide and hydrogen by the spark. they therefore sought to recombine the two latter gases by the discharge; in this they succeeded, and the action was more rapid than with the first. They also succeeded in producing ammonia from three volumes of hydrogen and one of nitrogen when treated in the same way; the action was most rapid when an acid was present to absorb the NH_3 as fast as it was formed.—On the physical and political history of Chili, by M. Gay, was a sketch of a work by the author in Spanish consisting of thirty volumes.—On the qualities necessary to the springs required for the supply of water to Paris by M. Belgrand.—M. Leymerie was then elected correspondent of the Mineralogical section in place of the late M. Haidinger, and M. Didion correspondent of the Mechanical section in place of the late Canon Moseley.—On a spectral illuminator, by M. F. P. Le Roux, described a new method of obtaining monochromatic illumination.—On the action of electricity on flames by M. Neyreneuf.—On the application of the curves *des debits* to the study of the laws of rivers and to the effects produced by a multiple system of reservoirs by M. de Graeff.—Observations on *Phylloxera vastatrix*, by M. Maxime Cornu.—A decree from the President of the Republic was received authorising the Academy to receive a legacy of 40,000 francs, left to it by the late Marshal Vaillant.—On the interference fringes observed in the case of Sirius and several other stars when large telescopes are employed; a consequence of the relative angular diameter of the stars in question, by M. Stephan. The author hopes, by means of certain observations, to obtain an approximate measurement of the diameter of Sirius.—On the comparison of electrical machines, by M. Mascart.—Remarks on the resistance of galvanometers, by M. J. Reynaud.—On the condensed discharge of the induction spark, by M. Th. du Moncel.—Researches on the chloride bromide and iodide of trichloracetyl, by M. H. Gal.—On the action of sodic sulphide on glycerin, by M. F. Schlagdenhauffen.—On a volumetric method of estimating oxygen in hydric peroxide and other liquids, by M. F. Hamel; this is an application of the disengagement of oxygen from the above body, by means of potassic permanganate. The gas liberated and the permanganate used form the data necessary for the preparation of standard permanganate solution, where the oxygen liberated per c.c. of reagent used is known. On the properties and composition of a cellular tissue which extends throughout the organism of the vertebrata, by M. A. Müntz.—Discovery of a new human skeleton of the paleolithic period in the caverns of Baoussé Roussé, by M. E. Rivière.—On the influence of various coloured rays on the spectrum of chlorophyll, by M. J. Chautard.—A note on the habits of "Lombrics," by M. E. Robert.

DIARY

THURSDAY, MAY 1.

ROYAL SOCIETY, at 8.30.—On the Effect of Pressure on the Character of the Spectra of Gases: C. H. Stearn and G. H. Lee.—On the Condensation of a Mixture of Air and Steam upon Cold Surfaces: Prof. Osborne Reynolds.—Further Observations on the Temperature at which Bacteria Vibriones and their supposed Germs are killed when exposed to Heat, &c.—Dr. Bastian.

SOCIETY OF ANTIQUARIES, at 8.30.—Flint Implements from Japan: W. L. Lawrence.—On Religious Guilds, and particularly the Privileged Guild at Walsoken, Norfolk: J. G. Nichols.

LINNEAN SOCIETY, at 8.—On Cinchonas: J. E. Howard.

CHEMICAL SOCIETY, at 8.—On Zirconia: J. B. Hannay.—On a new class of Explosives: Dr. Sprengel.

ROYAL INSTITUTION, at 2.—Annual Meeting.

FRIDAY, MAY 2.

A VOICE FROM CAMBRIDGE

IT is known to all the world that science is all but dead in England. By science, of course, we mean that searching after new knowledge which is its own reward, a thing about as different as a thing can be from that other kind of science, which is now not only fashionable, but splendidly lucrative—that "science" which Mr. Gladstone and Mr. Lowe always appeal to with so much pride at the annual dinner of the Civil Engineers—and that other "science" prepared for Jury consumption and the like.

It is also known that science is perhaps deadest of all at our Universities. Let any one compare Cambridge, for instance, with any German university; nay, with even some provincial offshoots of the University in France. In the one case he will find a wealth of things that are not scientific, and not a laboratory to work in; in the other he will find science taking its proper place in the university teaching, and, in three cases out of four, men working in various properly appointed laboratories, which men are known by their works all over the world.

This, then, is the present position of Cambridge after a long self-administration of the enormous funds which have been so long accumulating there for the advancement of learning. Cambridge no longer holds the place which is hers by right in the van of English science, her workers are few, and to those few she is careful to afford no opportunity of work, such as it is the pride of scholastic bodies in other countries to provide for the men who bring the only lasting honour to a university.

We have in what has gone before instanced Cambridge specially, as we have to refer to a step which has been recently taken there; but if the state of things is to be condemned at Cambridge, it must be admitted that it is only too recently that an attempt has been made to correct, in one direction, a similar state of things at Oxford.

What then do the Universities do? They perform the functions, for too many of their students, of first-grade schools merely, and that in a manner about which opinions are divided; and superadded to these is an enormous examining engine, on the most approved Chinese model, always at work, and then there are fellowships.

Now the readers of NATURE do not need to be informed that at the present moment there are two Royal Commissions inquiring into matters connected with the Universities, and that not long ago, at a meeting at the Freemasons' Tavern, the actual absence of mature study and research at the Universities, the lack of opportunities and buildings for scientific puposes, the apotheosis of the examining system, and the wanton waste of funds in fellowships, were unhesitatingly condemned by some of the most distinguished men in the country, many of them residents in the Universities.

Within the last week a memorial has been presented to the Prime Minister by persons engaged in University education at Cambridge, which on one of the points above referred to contains a most important expression of opinion; but we had better give the memorial *in extenso*:—

[Memorial.]

"We, the undersigned, being resident Fellows of Colleges and other resident members of the University of Cambridge engaged in educational work or holding offices in the University or the Colleges, thinking it of the greatest importance that the Universities should retain the position which they occupy as the centres of the highest education, are of opinion that the following reforms would increase the educational efficiency of the University, and at the same time promote the advancement of science and learning.

"1. No Fellowship should be tenable for life, except only when the original tenure is extended in consideration of services rendered to education, learning, or science, actively and directly, in connection with the University or the Colleges.

"2. A permanent professional career should be as far as possible secured to resident educators and students, whether married or not.

"3. Provision should be made for the association of the Colleges, or of some of them, for educational purposes, so as to secure more efficient teaching, and to allow to the teachers more leisure for private study.

"5. The pecuniary and other relations existing between the University and Colleges should be revised, and, if necessary, a representative Board of University Finance should be organised.

"We are of opinion that a scheme may be framed which shall deal with these questions in such a manner as to promote simultaneously the interests of education and of learning, and that any scheme by which those interests should be dissociated would be injurious to both."

This memorial reflects great credit upon the two out of seventeen heads of Colleges, and the majority of Professors, Tutors, Assistant-Tutors, and Scholars who have signed it. The only wonder is that some action to remedy a state of things which has been considered a scandal by many, both in and out of the University, who have had the best opportunity of studying it, should not have been taken before. But we think the memorial fails in one point, and we believe that Mr. Gladstone has hit the blot, for his carefully worded reply reads to us most ominous. "The time has scarcely arrived for bringing into a working shape proposals for extending and invigorating the action of the Universities and Colleges in connection with the more effective application of their great endowments." We see in the memorial too much reference to teaching, and too little to the advancement of learning.

Surely if the funds accumulated at our great Universities are to be merely applied to teaching purposes, the Government has the best possible argument for instantly requiring a very large proportion of the "great endowments" to be handed over, in order to endow other teaching bodies at present crippled for want of funds, and to create other teaching centres where now no teaching exists.

Might not the memorialists have taken a higher line, in which they would have been supported by all the culture of the country? Might they not have pointed out that the universities were once the seats of learning, and that the fact that they are now merely seats of teaching has arisen from a misapplication of the "great endowments" to

which Mr. Gladstone refers? Why should not the men of Cambridge say boldly that they wish their University to become again in the present what it was in the past? No government would dare to cripple such a noble work. As representing the then range of knowledge, and as seats of research centuries ago, our universities were unequalled; at present in both these respects they are ridiculous.

COUES' AMERICAN BIRDS

Key to North American Birds. By Elliott Coues, M.D. (Salem, U.S.)

THIS by no means small volume is intended to give a concise account of every species of living and fossil bird at present known from the continent north of the Mexican and United States boundary. The reputation of the author, who is so well known by his works on the sea-birds, and for the anatomy of the loon, cannot but be increased by this production, which illustrates on every page the extent of his general information, and the soundness of his judgment. The subject is treated in a manner rather different from that usually adopted by systematic ornithologists; less stress is laid on specific peculiarities, and more on the elucidation of the characteristics of the genera, families, and orders. There is a freshness and boldness in the manner in which the facts are handled, which will be extremely acceptable to those who look upon ornithology as a branch of natural history rather than an all-absorbing study of itself. We know of no work of the size which gives such a fair and reliable description of the reasons that have led to the limitation of the ranges of the larger divisions which now obtain, and their inefficiency is in many cases rendered but too evident. The introduction, occupying nearly seventy pages, incorporates much of the work of the illustrious Nitzsch, which is daily becoming more fully appreciated, though neglected so long. We are surprised to find that the labours of Mr. Macgillivray have not been here done equal justice to, for there cannot be a doubt that the peculiarities of the viscera are of as great importance in the classification of birds, and yet they are scarcely mentioned; in one instance we find it incorrectly stated that the cæca of the *Cathartidæ* are very small, the term must be here understood in its extreme sense, as they are absent altogether.

The descriptions of the genera are clear and concise; many of the peculiarities of the beak and primaries especially, are made more evident by the liberal introduction of excellent line drawings, as in the account of the genus *Vireo*, which is discussed much in detail; and in most cases a picture of the whole bird, or the head, is given. A key is appended for discovering the genera with facility, constructed on the same principle as those employed by botanists. The paucity of the avian fauna in the region discussed, in comparison to that of the Southern Continent, is made most manifest, and the few stragglers which have thence made their way north, serve well as illustrations of the classes which, were it not for them, would not find a place in a work on North American Birds.

FLAMMARION'S ATMOSPHERE

The Atmosphere. Translated from the French of Camille Flammarion, edited by James Glaisher, F.R.S., &c. (London: Sampson Low and Co., 1873.)

IN some respects the volume before us may be considered as the sequel to its equally sumptuous companion "The Forces of Nature." For the ordinary reader must have some acquaintance with physics intelligently to follow the disentanglement of the various forms of energy —the mingled play of which give rise to the phenomena of meteorology. Nevertheless, M. Flammarion writes so lucidly and pleasantly, that a totally unscientific person can read this work with enjoyment and instruction. On the other hand it contains much that will be of interest to the man of science, as well as to the mere *dilettante.*

The scope of the work is stated in the editor's preface. It treats of the form, dimensions, and movements of the earth, and of the influence exerted on meteorology by the physical conformation of our globe; of the figure, height, colour, weight, and chemical components of the atmosphere; of the meteorological phenomena induced by the action of light, and the optical appearances which objects present as seen through different atmospheric strata; of

FIG. 1.—Section of a hailstone enlarged.

the phenomena connected with heat, wind, clouds, rain, electricity; and also of the laws of climate. These subjects are illustrated by ten admirable chromo-lithographs, and upwards of eighty woodcuts, but many of these latter we observe have already done duty in other French treatises. The coloured illustrations are quite works of art; especially noteworthy are the representations of a sunset, of sunrise as seen from the Righi, and of a solar and a lunar rainbow. Science has more often given than received aid from art, but the pages of this book show how much service art can render to science. The printing is remarkably well executed.

The translation has been done by Mr. E. B. Pitman, and the task has been well discharged. The value of the original work is considerably increased by the careful revision it has received from Mr. Glaisher, and the additions by him of many useful foot-notes. The tendency of M. Flammarion, like other popular French writers, to run into grandiloquent language, has been in general suppressed; though still a few cases remain that might well have been pruned.

One of the important features in this book is the frequent graphic delineation of meteorological data. Take for example the representation of the decreasing rainfall in passing from tropical to polar regions.

In a similar manner is shown the increase of rain, according to altitude, but in this there is evidently a mistake in one of the figures. Following this woodcut is the representation of the comparative depths of rainfall at noticeable spots. Towering over the whole is the rainfall at the mountain station of Cherra-Poejen in India, where upwards of 50 *feet* of rain annually descend during the seven months of the rainy season.

The engravings of different forms of hailstones are interesting. Here are some that fell on different occasions At the four corners are represented hailstones that fel at Auxerre, on July 29, 1871. The small drawings are o the more usual form of hailstones. The two stones in the centre are taken from drawings exhibited to the Academy of Sciences at St. Petersburgh, in September 1863. These stones were ellipsoidal in shape; their surface when examined through a lens "had the aspect of six-fronted pyramids, and a section of the interior revealed the existence of a hexagonal network of meshes," which is here represented on an enlarged scale. The fact of the crystalline structure of ice palpably occurring in hail-stones, is a most interesting observation. Mere pressure

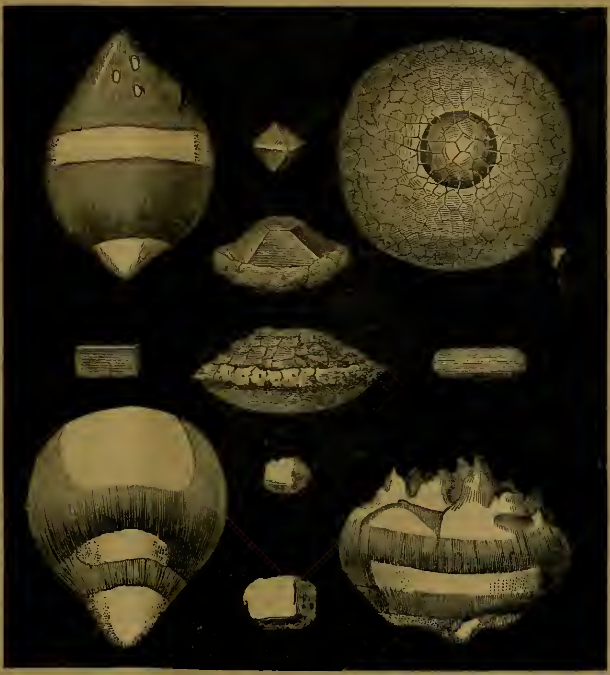

FIG. 2 —Different forms of hail.

of adjacent hailstones, like the pressure of soap-bubbles in a dish, would hardly produce such definite and regular hexagons.

As indicative of the labour Mr. Glaisher has bestowed on this work, we notice that all measurements are given in English equivalents, centigrade degrees are converted to Fahrenheit, Paris observations are replaced by data from Greenwich, and appropriate condensation and excision has reduced by one-half the unwieldy size of the original work.

Notwithstanding this evident care, several blemishes have escaped editorial revision. For example, the *ascent* of sound is given as the explanation of the ease with which sounds are heard in a balloon.

On p. 195 it is stated that "The sun's rays, after having traversed either the air, a pane of glass, or *any* transparent body, lose the faculty of retreating through the same transparent body to return towards celestial space." No reference is here made to diathermic bodies, such as rock-salt, concerning which this statement is wholly incorrect; and even as regards the most athermic substances, such as alum or water, a considerable

percentage of the sun's rays (its luminous portion, for example) would be re-transmitted. To explain electrical phenomena, M. Flammarion remarks, "It is admitted, first, that electricity is a subtle fluid capable of being amassed, condensed, and rarefied, &c.," and on p. 493, "The Saint Elmo fires are a slow manifestation of electricity, a quiet outflow, like that of the hydrogen in a gas-burner." At the present day we hardly expected to find so material a conception of electricity put forth, unguarded by a restriction of the fluid theory being merely a convenient hypothesis whereby electrical effects can be represented to the mind. And what evidence has M. Flammarion for his unqualified assertion on p. 427, that "the globe is one vast reservoir for this subtle fluid [electricity], *which exists in all the worlds appertaining to our system, and of which the radiating focus is in the sun itself. . . . Its palpitations sustain the life of the universe!*"

We have noticed a few other passages that have escaped the editor's attention in the present edition. The author speaks of a mist in the Grotto del Cane as "composed of carbonic acid gas, which is *coloured by a small quantity of aqueous vapour*." This is difficult to understand, the vapour being as invisible as the gas itself. We did not know it was necessary to use a "preparation of 'Joseph's paper,'" steeped in a solution of starch and potassic iodide, in order to detect ozone. In describing the discovery of oxygen and the chemical composition of the air, Lavoisier is the only name mentioned. It is not unlikely that a French writer should forget Priestley and Scheele, but the English editor ought hardly to have overlooked their names. We think also that a table of the analysis of air obtained from different parts of the globe should have been supplied. All that is given is one comparatively rough determination, namely, that 100 parts of air contain 23 of oxygen and 77 of nitrogen by weight. This is termed "an analysis made with every conceivable precaution." A large part of this same chapter is devoted to impurities present in the atmosphere, but Dr. Angus Smith's classical researches are not referred to, nor even is his name mentioned. And this reminds us that the volume is incomplete without an index, which it ought to possess.

We should like also to have seen some attempt at a collation of meteorological phenomena. Meteorologists in general seem to have their eyes so close to their special observations, that they accumulate a vast mass of figures without "hunting for a cycle," which has been asserted to be their first duty. There certainly appears to be some traces of an eleven-yearly cycle in the recurring period of extremely hot summers and cold winters from 1793 to the present time, cited by M. Flammarion. By collecting and tabulating these figures (given in chapters 4 and 5 of the third book), it becomes evident that extreme winters have immediately preceded or followed very hot summers. As the dates stand, they go alternately before and after, but this, no doubt, is but an accidental coincidence.

In spite of the slight defects we have pointed out, almost inseparable from a work dealing with such a variety of subjects, we can nevertheless endorse the opinion of the editor that the volume "will be found to be readable, popular, and accurate, and it covers ground not occupied by any one work in our language."

W. F. BARRETT

OUR BOOK SHELF

Mensuration of Lines, Surfaces, and Volumes. By D. Munn, F.R.S.E. (132 pp. "Chambers's Educational Course.")

THIS little work presupposes that the student has some knowledge of algebra and geometry, and we agree with the author that "it is not until a pupil has acquired this knowledge that he can take up the subject with any degree of intelligence or derive any educational advantage from its study." The number of propositions (59) is not too great; great judgment is displayed in the selection of the properties elucidated; the proofs are concise and clear, and are followed up by more than 350 examples, which appear to be clearly drawn up and to be well suited to test the student's acquaintance with the text. The book-work is accurately printed, the most important mistakes being p. 41, line 23, p. 91, lines 23, 24, and p. 110, line 22, but these are easily corrected. The work is one of a series, and the references throughout are to the edition of Euclid brought out by the same publishers; this reference to Euclid may appear objectionable in the eyes of some readers, but it is an objection easily got over in the case of those students for whom the work is intended.

Geological Stories. A series of autobiographies in chronological order. By J. E. Taylor, F.G.S. (London: Hardwicke, 1873.)

THE mere form into which Mr. Taylor has thrown his work—that of making a characteristic specimen from each geological formation tell its own story—has not, we think, added anything to its attractiveness: on the contrary, it will be apt to give many readers an uncomfortable feeling of unreality, and seems to us to have often cramped the author's freedom of description. We do not object to the autobiographical form in the abstract, but we think the direct form would have been more suited to Mr. Taylor's mental make. Notwithstanding this little drawback, Mr. Taylor tells the "old, old story," on the whole, in a manner well calculated to interest general readers, and send them to works where they may get the outline here given filled up. Anyone who reads this book carefully, will have a very fair notion indeed of what the best geologists think has been the earth's geological history. Mr. Taylor has of course wisely avoided entering upon disputed points, though one cannot but see that he has a comprehensive and very thorough knowledge of his subject. The illustrations are plentiful, though many of them seem well worn. On the whole the work is one we would recommend to be put into the hands of anyone who needs to be enticed into a knowledge of geology. "Stories" of this class are becoming more and more common every year. Not that we think or desire that they should ever supersede "stories" of another kind; but we take it as one of the most significant signs of the permeation of culture through society, that books of this class find a remunerative public.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Originators of Glacial Theories

THE writer of a notice of Tyndall's "Forms of Water" (NATURE, vol. vii. p. 400) blames Tyndall for having revived in a popular work the Forbes-Rendu controversy, and for calling attention to the claims of Agassiz and Guyot.

It seems rather curious that the attempt to give credit to scientific investigators for the share they may have had in the development of a great theory should be the occasion of fault-finding. No property is as subtle as scientific property, and the care Tyndall has bestowed upon the historical facts bearing

on the glacial theory in his various writings on glaciers, is in marked contrast to the ignorance of the true state of the case usually displayed by English authors, who ascribe to Forbes the sole credit of all recent progress in the glacial theory.

Forbes's work commenced in 1841; it was in that year that he made his memorable visit to the Glacier of the Aar, and there found Agassiz, who had at that time already spent five summers in the study of glaciers, and published in 1840 the preliminary part of the investigations carried on by himself and his companions ("Études sur les Glaciers").

Agassiz with his usual freedom in dealing with his associates, which has so often made him appear as following the lead of his pupils, freely imparted to Forbes all he had seen, and certainly had no idea that the hospitality so freely proffered would be returned by the proceedings of Forbes, who appropriated what he could, and misrepresented the nature of his intercourse with Agassiz while his guest on the Glacier of the Aar.

To Tyndall we owe a thorough sifting of the claims of each investigator on the subject, and however unpalatable it may be to national prejudices that the name of Forbes should play a secondary part in these investigations by the side of those of Venetz and Charpentier, Rendu and Agassiz, the fact remains the same, and every fair-minded investigator will thank Tyndall for what he has done. ALEX. AGASSIZ

Cambridge, Mass., April 15

Scientific Endowments and Bequests

IN the article on scientific endowments and bequests in NATURE for April 24, there is a statement, in reference to the Trinity Natural Science Fellowship, which perhaps requires a little correction.

Although there can be no doubt that the proposed new scheme for the selection of a fellow is in every way better than the old system of selection by routine examination, it is hardly right to speak of the election of a Natural Science Fellow, which took place in October 1870, as an "unsuccessful experiment."

It is certainly much to be regretted that circumstances have prevented the gentleman then chosen from strengthening the staff of scientific workers and teachers at Cambridge; but it is equally certain, that no system of selection that could possibly be desired, would have resulted in the election of a man possessed at once of more promising scientific abilities, and of a more genuine love for science.

The writer of the article seems to think that the examiners on that occasion were in search of what he is pleased to call a "genuine zoologist;" there is no doubt that there was then as there is now, a striking absence of young men of ability, devoting themselves to zoology; but though the college had announced a preference for a physiologist, yet the examiners were empowered to recommend either a zoologist, or one following any other branch of natural science. F. M. BALFOUR

Trinity College, Cambridge, April 20

Permanent and Temporary Variation of Colour in Fish

ONE or two episodes in the annals of the Brighton Aquarium for the week just ended deserve a passing note.

Among the Plaice, *Pleuronectes platessa*, added to the general collection, is one remarkable example, having the posterior half of its under surface, usually white, coloured and spotted as brilliantly as the upper one; the line of demarcation between these two colours again, though sinuous, is most abrupt, there being no shading through from one to the other as might have been anticipated. This specimen may be turned to good account by advocates of the Darwinian theory, as affording a remarkable instance of the occasional tendency of a specially modified type to revert to its primæval state—the Pleuronectidæ being derived from ancestors originally possessing bilateral symmetry, and an equal degree of coloration on each side.

As the spawning season advances, many of the fish, and more especially certain of the Acanthopterygian order, undergo various important modifications in both their habits and appearance. During the last week or so, many of the larger examples of the Black Bream, or Old Wife (*Cantharus lineatus*), exhibited in tank 4 on the north side of the Western corridor, have afforded a striking illustration of these phenomena. Hitherto their prevailing tint has been a delicate silvery blue, varied by irregular longitudinal lines of pale yellow, a hue scarcely in harmony with the name by which they are most popularly known. These light colours have now disappeared, or rather become absorbed, in a prevailing shade of deep leaden black, which, while deepest on the back, spreads itself over the whole surface of the fish with the exception of a few transverse lighter bands in the region of the abdomen. The males in particular are most conspicuous for this change, and these retiring from the remainder of the shoal, select certain separate and prescribed areas at the bottom of the tank, where they commence excavating considerable hollows in the sand or shingle, by the rapid and powerful action of the tail and lower portion of their body. A depression of suitable size having been produced, each male now mounts vigilant guard over his respective hollow, and vigorously attacks and drives away any other fish of the same sex that ventures to trespass within the magic circle he has appropriated to himself. Towards his companions of the opposite sex his conduct is far different; many of the latter are now distended with spawn, and these he endeavours by all the means in his power to lure singly to his prepared hollow, now discovered to be a true nest or spawning bed, and there to deposit the myriad ova with which they are laden, which he then protects and guards with the greatest care. Whether the aggregated produce of a large number of females is thus consigned to one bed, and whether the ova are guarded by the male until the young fish make their appearance, are points which, while awaiting confirmation, may be almost confidently inferred, reasoning from the very analogous nest-forming habits of the *Gasterosteidæ* or Stickleback family, already so familiar to every naturalist. The male of the Lump fish (*Cyclopterus lumpus*) is said to watch over the spawn of the female in a very similar manner, and at the particular time of the year, early spring, when it is deposited, assumes the most lively tints of red and blue, which disappear again after his paternal duties have been discharged, and are not retained through life as has been formerly supposed. On this point we have direct evidence from specimens confined within the aquarium walls. For yet another instance of change of colour in the male fish, associated with its nest-forming habits in the same Acanthopterygian order, I am indebted to a recent visit to the aquarium at the Crystal Palace, where Mr. Loyd directed my attention to a male example of the Cuckoo Wrasse (*Labrus mixtus*), which had formed a deep hollow in the sand of its tank, and was endeavouring in the most persuasive manner to induce a female of the same species to share it with him, swimming backwards and forwards between her and the completed nest, and plainly exhibiting the greatest anxiety for her to follow. The normal brilliancy of this fish was supplemented by a light opaque patch that extended over a considerable portion of the back of his head and shoulders, while the tints of the remaining portion of the body were more than ordinarily deepened.

W. SAVILLE KENT

On Approach caused by Velocity and Resulting in Vibration

PROF. J. CLERK-MAXWELL, in his recent paper on "Action at a Distance," has brought under notice again the experiments of Prof. Guthrie "On Approach caused by Vibration," and has so well summarised in popular language the facts investigated and the conclusions arrived at, that fitting opportunity appears to present itself to me for calling the attention of the scientific world to phenomena closely allied to those under review although more complex in their manifestation, since in these velocity is independent of, yet initiates vibration. That they have not been referred to in the experiments either by Prof. Guthrie, Challis, and others who have taken part in the discussion is probably to be accounted for in the unfortunate although convenient habit indulged in by experimentalists of using the tuning fork as the agent for demonstration.

The following passage from Prof. J. Clerk-Maxwell's paper alluded to will best introduce my own observations—" Here is a kind of attraction with which Prof. Guthrie made us familiar. A disc is set in vibration and is then brought near a light suspended body which immediately begins to move towards the disc as if drawn towards it by an invisible cord. What is this cord? Sir W. Thomson has pointed out, that in a moving fluid the pressure is least where the velocity is greatest. The velocity of the vibratory motion of the air is greatest near the disc. Hence the pressure of the air on the suspended body is less on the side nearest the disc than on the opposite side; the body yields to the greater pressure and moves towards the disc. The

disc therefore does not act where it is not. It sets the air next it in motion by pushing it, this motion is communicated to more and more distant portions of the air in turn and thus the pressures on opposite sides of the suspended body are rendered unequal, and it moves toward the disc in consequence of the excess of pressure. The force is therefore a force of the old school, a case of *vis a tergo*, a *shove* from behind."

It has been customary with me for several years, when occasion invited it, to demonstrate to my musical friends the physical action existing in the sounding organ-pipe, to show them (taking up a chance wood-shaving lying on the floor of the workshop or a strip of tissue paper) that, heterodox though the teaching be, the stream of air at the mouth of the organ-pipe constitutes a free-reed—visibly ; before them the film-like wood-shaving is drawn into the motion of the air, and the beautiful curve of the reed's swing displays itself beyond dispute ; then to show them that the air-moulded tongue obeys every law of the free-reed, has its own definite rate of vibration, that the current is so directed that it shall *pass* not *strike* the lip, that it is an air-moulded or aëroplastic reed as definitely fashioned in substance, strength, proportion, and form, as metal reeds are to produce a required and determinate rate of vibration. First, the velocity of current, a constant upward force ; then, the periodicity of vibration as a *secondary* mode of its activity. The aëroplastic reed forming with the pipe a *system* of transverse vibration associated with longitudinal vibration, and possibly another phase of vibration across the width of the reed enabling it to synchronise with the harmonic range of the pipe ; the principle of action of the whole being termed, in my non-academic phraseology, suction by velocity ; but if a more exact expression is found its explanation should imply, or better still, include the axiomatic phrase of Sir W. Thomson, "in a moving fluid the pressure is least where the velocity is greatest." To state the existence of an air-moulded free-reed is to give the key to its nature. Flutes, flageolets, whistle-pipes, disc-whistles, form one group with organ-pipes ; all are of one type. Then there is another group of free-reeded instruments including the vocal organs, the trumpet, bassoon, oboe, harmonium, and the like, the only distinction between the two groups being that the one possesses reeds of air of definite pitch ; and the other possesses reeds of grosser substance, whether it be membrane wood or metal, alike of definite pitch, but in every one the degree of elasticity or pliancy in the substance determines how much of that pitch shall be maintained as the work is done. Velocity is power, and in every conjunction of reed and pipe the reed is the dominant. Most distinctly it should be recognised that the air-reed does *work* and expends power in doing it. A rod or a string delivers up under a single blow the whole vibrating energy it is capable of—not so the air-column in the organ-pipe, which needs to be beaten the precise number of blows requisite for the pitch of tone elicited.

Reeds of the oboe are as truly free-reeds as are the vocal cords. The stream of air does not necessarily pass down the organ-pipe, but in the oboe it is essential it should pass down the pipe. The action of this orchestral instrument is best explained under the law of "least pressure," showing an identity in principle but with difference of mode ; instead of the stream with a lapping action as an air-tongue at the mouth of the organ-pipe, we have an air-current passing between two sensitive reeds down a narrow straw-like tube into the main body of the pipe. The velocity in the little tube immediately causes "least pressure" in the interior, effecting approach and closure of the pair of lip-like reeds, and so on, a perpetual renewing and breaking of contacts, the periodicity of such movement being determined by the sensitiveness of the reed in relation to the air-tube through which the impulses must move before the "dispersion of the vibrations" into the air *relieves* the reed and fixes the *period* of its stroke. In further proof that the flue organ-pipe is a free-reed instrument, compare the flute, its representative, with the oboe and clarionet. So little is understood concerning the nature of these wind instruments, that, whenever in the science of acoustics they are referred to, it is stated that the clarionet is a closed pipe, and the oboe an open pipe ; that the former produces the series of uneven harmonics and the latter the even series, and the explanation given is that the tube of the one is cylindrical, and the tube of the other is conical. The explanation does not really explain. It is true that the clarionet gives in relation to its length the pitch corresponding to that of a closed pipe, whilst the oboe, though of similar length (scale of key allowed for), is of the pitch of an open pipe, with relative harmonics ; yet this difference arises not in any degree from the shape of bore cylindrical or conical. As well denominate the oboe "a closed pipe" if structure is compared ; the one is not more a closed pipe than the other, the true cause of the diversity is in the rate of *reed-vibration* of the clarionet being only half the rate of that natural to the oboe. The proof is clear and open to anyone intent to observe. Place the oboe head on the clarionet-tube, and you will get from this same tube only the two-feet tone instead of the four-feet tone, and with this transformation of pitch the series of harmonics previously wanting. Place the flute-head on the clarionet-tube and the same results follow ; showing that the velocity of vibration originates with the reed, and that the flute rightly considered is a free-reeded instrument.

The experience of years justifies me in presenting these conclusions, and should they not be disproved, questions will suggest themselves whether physicists should not look to the disturbance of the equilibrium of air-pressure as the chief element in determining the pitch of sounds produced in organ pipes ; whether the long conserved doctrine of "the column of air within being alone the cause of sound" has not been detrimental to investigation as was in older times the doctrine that "nature abhors a vacuum," which, as Whewell points out, retarded science a century by pre-occupying men's minds against observation ; and whether it is not through the presence of the law of "least pressure" that vibration of any kind becomes possible.

HERMANN SMITH

The Hegelian Calculus

YESTERDAY evening a copy of NATURE for the 10th instant, sent to my late address at Piershill, reached me here. The sender annexes the initials W. R. S.—those, presumably, of Mr. W. R. Smith. It was only thus that I became aware of that gentleman's letter on "The Hegelian Calculus," in said issue ; and, as I am called upon by name therein, I should be obliged if, in an early number of the valuable publication referred to, you would kindly allow me insertion of this explanatory word in return.

In my rejoinder, mentioned by Mr. Smith as appearing in the current number of the *Fortnightly*, and which (rejoinder) treats, as Mr. Smith truly says himself, his own paper in the same pages "as a virtual concession of the entire case," I speak thus :—

"He that, with whatever tincture of mathematics, will but cast a single glance into the situation as it veritably is, will perceive at once that Mr. Smith's present paper is of such a character as not to demand any further answer from me. It is of such a character, however, that it may be put on the level of a business transaction, and if Mr. Smith can persuade any competent mathematician—say the greatest alive, Sylvester, he being at once mathematician, metaphysician, and German scholar, and at the same time wholly unknown to myself—if, I say, Mr. Smith can persuade any such competent expert to see in this matter with Mr. Smith's eyes, I shall consent to be mulcted in what pecuniary penalty this expert may please."

Of course with reciprocity in the other event. I hope Mr. Sylvester will kindly pardon me for having thus, almost involuntarily, made free with his name ; but, if I could say the above then, certainly not less can I say the above now—after this letter of Mr. Smith's. The "character" in allusion is one, I believe, hitherto unexampled in literary controversy, and such that, as I also believe, the most important interests call forth thorough understanding of it. It is in consequence of this "character" that, as I have intimated, I cannot, with any respect to myself, enter into further direct relations with Mr. Smith, and that I must confine myself to what has been said above. All, for that part, may be confidently left to time. Napoleon snipped off, and put in his pocket the alleged gold tassel, assured that use would disclose the tinsel in suspicion. So, as regards the—to me—extraordinary operations of Mr. Smith—not but every *Kenner* must see what is concerned at a glance—I can leave them fearlessly to the intromissions of the public.

Further proceeding, let me intimate in conclusion, however formidable it may look, must, so far as I am concerned, be arranged by a friend on the one part, and a friend on the other. Longer to trouble the public with these altercations can only seem to it impertinent. I, at least, shall be satisfied if it will but consider the result in the end.

Edinburgh, April 18 J. HUTCHISON STIRLING

Moving in a Circle

I HAD to cross a very large flat field in Lincolnshire one evening; the ground covered with snow, and there being a dense fog. I knew my way perfectly; but on coming to the hedge found that I had deviated *to the right.* Next day I had occasion to re-visit my track and found that I had described about one quarter of a circle. T. M. W.

JUSTUS LIEBIG

JUSTUS LIEBIG was born at Darmstadt, the native place of many eminent chemists, May 13, 1803; died at Munich, April 18, 1873.

As generations pass away, and the deeds and capacities of great men come to be truly estimated, it will be found that the name of Liebig claims a position very close to those of Lavoisier and Dalton, the greatest leaders in our science. It is not as the author of the 317 investigations the titles of which fill the pages of the Royal Society catalogue, nor even as the father of organic chemistry, nor as the great originator of a scientific physiology and agriculture, nor again as the writer of numerous handbooks, that Liebig has done most for science; his greatest influence has been a personal one, for it is to him that most chemists now living either directly or indirectly owe their scientific existence. The Giessen Laboratory was the first one in which our science was truly taught, and from this centre the flame of original research was carried throughout all lands by ardent disciples who more or less successfully continued, both as regards tuition and investigation, their master's work.

Liebig early showed his love for experimental inquiry, and his father apprenticed him—as was then usual in the case of boys who exhibit such tastes—to an apothecary. Ten months of the shop drudgery was sufficient to convince the boy that this sort of life was not what he required, and it is said that he ran away from his pill-making; at any rate, he returned to his home in Darmstadt, and soon entered the University of Bonn, and afterwards that of Erlangen, where he met with congenial spirits, and continued his scientific education. At that time (1822), however, the German universities were almost destitute of means of stimulating research, or even of imparting a knowledge of existing science in its higher and more modern forms; and for this reason the steps of all young German chemists were naturally turned towards Paris, where Gay Lussac, Thenard, Dulong, and other well-known masters were working and teaching. In 1822, being nineteen years of age, Liebig had already made himself known in his native town and to its paternal government by the investigation of the action of alkalies on fulminating silver, as well as by other publications on the composition of certain colouring materials; and the Grand Duke, anxious to promote the glory of his capital, gave his promising young townsman the means of studying in Paris. There Liebig, thanks to the friendly introduction of Alexander von Humboldt, was allowed to work in Gay Lussac's private laboratory, where he completed his investigation on fulminic acid, and became acquainted with Gay Lussac's methods of exact investigation. In Paris, too, he met Mitscherlich and Gustav Rose, and the intercourse with them and other men of science which he there enjoyed confirmed him in the choice of his profession, and in 1824 he returned home and was appointed, when twenty-one years of age, Extraordinary, and two years afterwards the Ordinary Professor of Chemistry at Giessen, the University of his country, and the scene of the great labours and triumphs of his life.

The influence which Liebig has exerted on the progress of discovery in our science is due to his possession of that peculiar gift essential to all great investigators of nature, which unites to indomitable perseverance in following out experimental details, the higher power of generalisation. His indefatigable energy in experimental investigation must be known to all who have even turned over the pages of his Annalen; there is scarcely a volume in the thirty years dating from the commencement of the journal in 1832 to 1862, which does not contain some important record of his labours, and in the height of his power the number of independent researches which he was able to carry out at once is certainly marvellous. A mere list of even the most important of his investigations in the one branch of organic chemistry would be far too long for a brief notice such as this; it may, however, be well to call to mind his productivity during the first few years of the Giessen career. In the first rank amongst his earlier researches, and serving as a necessary basis for the whole, come those in which he placed the analysis of organic substances upon a firm and simple basis. His final description of the apparatus is worth remembering—"There is nothing new in this arrangement but its simplicity and perfect reliability." The attack on this subject, commenced in conjunction with Gay Lussac in 1823, was not completed by himself till 1830; but then he furnished chemists with the simple and effectual methods which, with slight modifications, we still employ. Thus armed, the secrets of the composition of the organic acids and alkaloids were soon revealed, and among the most important discoveries we have first amongst the acids, fulminic (1822), cyanic (1827), hippuric (1829), malic, quinic, rocellic and camphoric (1830), lactic (1832), aspartic (1833), uric (1834), then we find chloral and chloroform (1831), acetal (1832), aldehyde (1835).

In 1837 he published, in conjunction with Dumas, a paper, "Note sur la constitution de quelques acides," in which for the first time the theory of polybasic organic acids was put forward. Graham's researches on the phosphates proving the polybasic character of phosphoric acid having been published in 1833. In a research on the constitution of these bodies published in 1838 this was more fully worked out, and Davy's previously expressed views as to the part played by hydrogen confirmed and supported. His researches on the cyanogen derivatives (1834), on the chlorine substitution-products of alcohol (1832), and those carried on for so many years in conjunction with his life-long friend Wöhler, as on the composition of sulphovinic acid (1832), and especially that on the derivatives of benzoic acid (1832) sufficed to place the theory of organic radicals on a firm basis. Then too we must not forget their conjoint researches, chiefly carried on by correspondence between Giessen and Göttingen on the oxiacids of cyanogen (1830), a most difficult subject worked out in a masterly way, or that on the formation of benzoyl hydride from amygdalin in the bitter almond (1837), or again the memorable investigations on the nature of uric acid and the products of oxidation of this substance by nitric acid (1838), in which not only a large number of new bodies are described and allantoin artificially prepared, but system and order introduced among the whole.

One of his favourite subjects was that of Fermentation, and his explanation of the phenomena as being due to the action of a substance whose molecules are in a state of motion upon the fermentable body is yet well known, though now in the minds of most supplanted by the germ theory of Pasteur.

As a critic Liebig was sharp, satirical, and sometimes even unsparing and bitter, especially when his own views were assailed; his anonymous critiques are brimfull of good-humoured satire, whilst in others to which he gives his name, he lashes his victim most unmercifully. Who can read his "Das enträthselte Geheimniss der geistigen Gahrung" "Vorläufig briefliche Mittheilung," 1839, without amusement? His description of the minute organisms having the form of a Beindorfschen Destillirblase (ohne den Kühlapparat) feeding on sugar and excreting alcohol

(aus ein rosenroth gefärbten punkt), and carbonic acid (aus dem Harnorganen) will be long remembered, and even at the present day the satire has not lost its applicability. Then again in a letter purporting to be written from Paris and signed S. C. H. Windler, though doubtless written by Liebig, he laughs to scorn the idea that the theory of substitution, which he himself upheld, could be so far extended as was by some chemists believed possible. In this letter he states, as the last great discovery of the French capital, that it had been found possible to replace in acetate of manganese, first the atoms of hydrogen by chlorine, then the atoms of oxygen, then those of manganese, and lastly that even the atoms of carbon had been replaced by this gas. So that a body was in the end obtained, which, although it contained nothing but chlorine, still possessed the essential properties of the original acetate of manganese. He adds in a note: "Je viens d'apprendre qu'il y a déjà dans les magasins à Londres des étoffes en chlor filé, très recherchés, dans les hôpitaux, et préférés à tout autres pour bonnets de nuits, calecons, etc.!"

Those who wish to read an unsparing critique, may turn to Liebig's remarks on Gerhardt (1846), to those on Mulder as regards his protein theory, or again on Gruber and Sprengel respecting a review of his own book on Organic Chemistry (1841). It was not in Liebig's nature to spare either private persons or Governments when he thought that science would be advanced by plain speaking. In his two papers on "Der Zustand der Chemie in Oestreich" (1838), and in "Preussen" (1840), whilst he points out the shortcomings of both countries, bravely asserts, in the strongest terms, the dependence of national prosperity upon original research, a subject concerning which in England, *most people, thirty years later (to our shame be it said) are altogether in the dark!*

Other and wider questions, to the solution of which Liebig in later life turned his energies, were those respecting the establishment of a Scientific Agriculture, and the foundation of a new science of Physiological Chemistry. It is in this direction that his labours are best known to the general public in England; and there is no doubt, although in many details his views have since proved erroneous, that he was correct in the main issues, and that the stimulus given to British agriculture through Liebig's writing and investigations, has been of the most important kind. Agriculturists have thus been made aware that a scientific basis for their practice exists which, if not as yet complete, can still explain much in their art of what had previously depended on mere empiricism. Then, again, the interest and attention which were thus brought to bear on these subjects, has led to the establishment of Agricultural Colleges and "Versuchs-Stationen," and to the carrying out of researches like those magnificent ones of Lawes and Gilbert, from which we are receiving information concerning the various questions relating to plant life such as long-continued investigation and observation alone can yield.

In the year 1852, having lectured for sixty semestres in Giessen, he left the university to which he had given a world-wide fame, to become the centre of a galaxy of men of science whom Maximilian II. of Bavaria had called to Munich. There, having built himself a good laboratory and a spacious house adjoining, he spent the remainder of his days in quiet labour and well-earned and honoured repose. The active period of his life having passed, he entirely withdrew from discussions on purely theoretical questions, and occupied himself with investigations chiefly of a practical character, such as those on the extract of meat, and on infants' food. He continued to re-edit his various books, indulging occasionally in his old habit of a sharp hit at the views of some scientific brother. His last investigation and critical discussion of the labours of other chemists was published in 1870, "On Fermentation and the Origin of Muscular Force." In this he strenuously upholds his old theory of fermentation against Pasteur's explanation of the phenomena, and his views and arguments are as forcibly and clearly expressed as we find them in his early publications. The last of his hundreds of communications to the Annalen is a notice on the discovery of chloroform, published in March of last year, in which he calls attention to the fact that the discovery of this important substance is due to himself in 1831, and not to Soubeiran, as is generally supposed, although Liebig overlooked the small quantity of hydrogen (0·8 per cent.) which chloroform contains, and termed it a chloride of carbon.

As an author, Liebig is remarkable for the lucidity and grace of his style. The best examples of this are to be found in his "Familiar Letters on Chemistry." His mode of popular treatment of a somewhat obscure subject is seen in the well-known chapter (xxiv.) in his "Familiar Letters," on "Spontaneous Combustion of the Human Body." He there goes step by step through all the better authenticated cases, shows the want of sufficient evidence in each case, points out the fallacies of the theories proposed to explain them, and concludes with proving, by the application of known physical and chemical laws, that the supposed phenomena cannot possibly occur.

Looking once more back upon the labours of Liebig, we again come to the conclusion that the chief and characteristic glory of his life is the impulse which he gave to the study of our science and the personal influence which he exerted among his numerous and distinguished pupils.

The present short and imperfect sketch of the scientific bearings of a great life is not one in which personal qualities can be discussed; suffice it to say that though Liebig was an awkward adversary, he was a faithful friend, and always ready and anxious to assist deserving merit.

H. E. ROSCOE

NOTES FROM THE "CHALLENGER"

WE left Santa Cruz on the evening of Friday, the 14th of February. The weather was bright and pleasant with a light breeze—force equal to about 5—from the north-east. Our course during the night lay nearly westward, and on the morning of the 17th we sounded, about 75 miles from Teneriffe, and 2,620 miles from Sombrero Island, the nearest point in the Virgin group, in 1,891 fathoms, with a bottom of grey globigerina ooze, mixed with a little volcanic detritus. The average of two Miller-Casella thermometers gave a bottom temperature of 2° C.

The slip water-bottle which was used by Dr. Meyer and Dr. Jacobsen in the German North-Sea Expedition of last summer was sent down to the bottom, and Mr. Buchanan determined the specific gravity of the bottom water to be 1·02584 at a temperature of 17°·9 C., the specific gravity of surface water being 1·02648 at a temperature of 18°·5 C.

All Sunday, the 16th, we spent sailing with a light air from the northward, and by Monday morning we had made about 130 miles from our previous sounding. The dredge was put over at 5.15 A.M. with 2,700 fathoms rope, and a weight of 2 cwt. 300 fathoms before the dredge.

After steaming up to the dredge once or twice, hauling-in was commenced at 1.30 P.M., and the dredge came up at 3.30 half full of compact yellowish ooze. The ooze was carefully sifted, but nothing was found in it with the exception of foraminifera, some otolites of fishes, some dead shells of pteropods, and one mutilated specimen of what appears to be a new Gephyrean. This animal has been examined by Dr. von Willemœs-Suhm, who finds that it shows a combination of the character of the Sipunculacea and the Priapulacea. As in the former group, the excretory orifice is near the mouth, in the anterior part of

the body, while, as in the latter, there is no proboscis and there are no tentacles. The pharynx is very short, and is attached to the walls of the body by four retractor muscles. The pharynx shows six to seven folds ending in a chitinous border. The mouth is a round aperture, beset with small cuticular papillæ. The perisom is divided into four muscular bands, the surface large, showing a tissue of square meshes, in each of which there are four to five sense-bodies. For the reception of this singular species Dr. von Willemœs-Suhm proposes to establish the genus *Leioderma*, which will represent a family intermediate between the Sipunculids and the Priapulids.

On the 18th we sounded at 9 A.M. in 1,525 fathoms, lat. 25° 45′ N., long. 20° 12′ W., 160 miles S.W. of the Island of Ferro, and 50 miles to the west of the station of the day before, in 1,525 fathoms. The "Hydra" tube brought up no bottom, and we sounded again with a depth of 1,520 fathoms, and again no bottom. It thus seemed that we had got upon hard ground, and as the sounding of the following day gave 2,220 at a distance of only 19 miles, we had evidently struck the top of a steep rise. The dredge was lowered at 10 A.M. with 2,220 fathoms of line and 2 cwt. leads 300 fathoms before the dredge. At 5.30 P.M. the dredge was hauled up, and contained a few small pieces of stone resembling the volcanic rocks of the Canary Islands, and some large bases of attachment and some branches of the calcareous axis of an Alcyonarian polyp allied to *Corallium*. Some of the larger stumps were nearly an inch in diameter; the central portion very compact, and of a pure white colour: the surface longitudinally grooved, and of a glossy black. The pieces of the base of the coral which had been torn off by the dredge were in one or two cases several inches across and upwards of an inch thick, forming a thick crust from which the branches of the coral sprang. The crust was of a glossy black on the surface, showing a fine regular granulation, and a fracture through the crust was of a uniform dark brown colour and semi-crystallised. The whole of the coral was dead, and appeared to have been so for a long time. It was so fresh in its texture, however, that it was scarcely possible to suppose that it was sub-fossil, although from the comparatively great depth at which it was found, and the many evidences of volcanic action over the whole of this region, one could scarcely avoid speculating whether it might not have lived at a higher level and been carried into its present position by a subsidence of the sea-bottom. I hope we may have an opportunity of determining this question in returning over the same ground later in the season.

Attached to the branches of the coral there were several specimens of a magnificent sponge belonging to the Hexactinellidæ. One specimen, consisting of two individuals united together by their bases, is about 60 centimetres across, and has very much the appearance of the large example of the tinder-fungus attached to the trunk of a tree (Fig. 1). Both surfaces of the sponge are covered with a delicate network of square meshes closely resembling that of *Hyalonema*, and formed by spicules of almost the same patterns. The sponge is bordered by a fringe of fine spicules, and from the base a large brush of strong, glassy, anchoring spicules project, fixing it to its place of attachment. The form of the barbed end of the anchoring spicules is as yet unique among sponges. Two wide, compressed flukes form an anchor very much like that of one of the skin-spicules of *Synapta*. The sponge when brought up was of a delicate cream colour. It was necessary to steep it in fresh water to free it from salt, and the colour changed to a leaden grey. A number of small examples of the sponge, some of them not much beyond the condition of gemmules, were found attached to the larger specimens and to branches of the coral, so that we have an opportunity of studying the earlier stages of its development.

For this sponge, which forms the type of a new genus, I propose the name *Poliopogon*[1] *amadou*.

Attached to the sponge were two examples of a fine Annelid which Dr. v. Willemœs-Suhm refers to the family Amphinomidæ, sub-family Euphrosyninæ, with many of the characters of the genus *Euphrosyne*. The body is 12 mm. long and 5 mm. broad, and consists of fifteen segments. The surface of the head is covered with a caruncle extending over the anterior segments, and the whole surface is clothed with milk-white two-branched setæ, which radiate over each segment like a fan.

On the following day a series of temperatures were taken from the surface to 1,500 fathoms at intervals of 100 fathoms.

Depth.	Temp.	Depth.	Temp.
Surface	19°·5C.	800 fathoms . .	5°·6C.
100 fathoms . . .	17·2	900 ,, . . .	4·7
200 ,, ...	13·7	1000 ,, . . .	4·6
300 ,, ...	11·0	1100 ,, . . .	3·8
400 ,, ...	9·5	1200 ,, . . .	3·5
500 ,, ...	7·6	1300 ,, . . .	3·1
600 ,, ...	6·5	1400 ,, . . .	2·8
700 ,, ...	6·2	1500 ,, . . .	2·6

The dredge was not used, but, as is our custom whenever the rate of the ship is such as to make it practicable, a large towing-net was put out astern.

In hot, calm weather the towing-net is usually unsuccessful. It seems that the greater number of pelagic forms retire during the heat of the day to the depths of a few fathoms, and come up in the cool of the evening and in the morning, and in some cases in the night. The larger phosphorescent animals are frequently abundant during the night round the ship and in its wake, while none are taken in the net during the day. Mr. Moseley has been specially engaged in working up the developmental stages of *Pyrosoma*, and the intricate structure of the tissues and organs of some of the surface groups, whose extreme transparency renders them particularly suitable for such researches.

Feb. 21.—Up to 2.15 P.M. sailing under all plain sail at the rate of six knots an hour before the N.E. trades, force 3 to 4.

The dredge was put over at 5 P.M. with 3,400 fathoms of line, and was kept down till one o'clock A.M. on the following morning, the ship drifting slowly. Our position at noon on the 21st was about 500 miles S.W. of Teneriffe, lat. 24° 22′ N., long. 24° 11′ W., Sombrero Island S. 58° W. 2,220 miles. Work began early on the 22nd, and the dredge, which had begun its ascent at 1.15 A.M., came up at 5.45 half full of a yellowish ooze, which was not so tenacious as usual, and on the whole singularly poor in higher living things. A careful and laborious sifting of the whole mass gave us three small living mollusca, referred to the genera *Arca*, *Limopsis*, and *Leda*; and two Bryozoa apparently undescribed. Foraminifera were abundant, many examples of miliolines being of unusually large size. Some beautiful radiolarians were sifted out of the mud. These may have been taken into the dredge on its way up, or more probably they may have lived on the surface or in intermediate water and have sunk to the bottom after death, since they consist of continuous fenestrated shells of silica.

On Tuesday the 25th a small dredge was lowered at 6.30 A.M. with 3,500 fathoms of line (2,500 fathoms of $2\frac{1}{2}$ in. rope and 1,000 of 2-in.), and 2 cwt. leads attached 300 fathoms in advance. At 7.30 we sounded in 2,800 fathoms, with a bottom of the same reddish ooze, and a temperature of 2° C. A series of temperatures were taken at intervals of 100 fathoms down to 1,000, the result agreeing closely with those of the previous series. At 5.15 P.M. the dredge came up clean and empty. It had either never reached the bottom, owing to some local current or the drift of the ship, or else everything had

[1] Πολιός, white, and πώγων, a beard.

been completely washed out of it on its way to the surface. The bottom water gave a specific gravity of 1·02504 at 19°·6 C., that of the surface being 1·02617 at 21°·3 C. While sounding, the current-drag was tried, and indicated a slight north-westerly current.

As the attempt to dredge on the previous day had been unsuccessful, it was determined to repeat the operation with every possible precaution on the 26th. The morning was bright and clear, and the swell, which had been rather heavy the day before, had gone down considerably. A sounding was taken about 10 o'clock A.M. with the "Hydra" machine and 4 cwt. The sounding was thoroughly satisfactory, a sudden change of rate in the running out of the line indicating in the most marked way when the weight had reached the bottom. During the sounding a current-drag was put down to the depth of 200 fathoms, and it was then ascertained that, by means of management and by meeting the current by an occasional turn of the screw, the ship scarcely moved from her position during the whole time the lead was running out. The depth was 3,150 fathoms; the bottom a perfectly smooth red clay, containing scarcely a trace of organic matter—merely a few coccoliths, and one or two minute granular masses. The thermometer indicated a bottom temperature of 1°·9 C.

The small dredge was sent down at 2.15 P.M. with two hempen tangles; and, in order to ensure its reaching the bottom, attached to the iron bar below the dredge which is used for suspending the tangles, a "Hydra" instrument with detaching weight of 3 cwt. Two additional weights of 1 cwt. each were fixed to the rope 200 fathoms before the dredge. 3,600 fathoms of rope were payed out—1,000 fathoms 2 in. in circumference, and the remainder (2,600 fathoms) $2\frac{1}{2}$ in. The dredge came up at 10.15 P.M. with about 1 cwt. of red clay.

This haul interested us greatly. It was the deepest by several hundred fathoms which had ever been taken, and, at all events coincidentally with this great increase in

FIG. 1.—POLYOPOGON AMADOU Wy. T. Base

depth, totally different from what we had been in the habit of meeting with in the depths of the Atlantic. For a few soundings part of the ooze had been assuming a darker tint, and showed on analysis a continually lessening amount of calcareous matter, and, under the microscope, a smaller number of foraminifera. Now calcareous shells of foraminifera were entirely wanting, and the only organisms which could be detected after washing over and sifting the whole of the mud with the greatest care, were three or four foraminifera of the Cristellarian series, with their tests made up of particles of the same red mud. The shells and spines of surface animals were entirely wanting; and this is the more remarkable as the clay-mud was excessively fine, remaining for days suspended in the water, looking in colour and consistence exactly like chocolate, indicating therefore an almost total absence of movement in the water where it is being deposited. When at length it settles, it forms a perfectly smooth red-brown paste, without the least feeling of grittiness between the fingers, as if it had been levigated with extreme care for a process in some refined art. On analysis it is almost pure clay, a silicate of alumina and the sesquioxide of iron, with a small quantity of manganese.

It is of course a most interesting question whether the peculiar nature of this deposit is connected in any way with the extreme depth. I am certainly inclined at present to believe that it is not. The depth at Station 5 was 2,740 fathoms, and on that occasion foraminifera were abundant, and several bivalve mollusca were taken living. I cannot believe there can be any difference between a depth of 2,740 fathoms and one of 3,150 so essential as to arrest the life of the organisms to the secretions of whose tests the grey Atlantic ooze is due. I am rather inclined in the meantime to attribute this peculiar deposit to the movement of water from some special locality—very possibly the mouths of the great South American rivers—the movement possibly directed in some measure by the form of the bottom. This, however, is a question for the solution of which we may hope to procure sufficient data.

WYVILLE THOMSON

ON THE ORIGIN AND METAMORPHOSES OF INSECTS *

III.

THE INFLUENCE OF EXTERNAL CONDITIONS ON THE FORM AND STRUCTURE OF LARVÆ

THE facts recapitulated very briefly in the preceding chapters show, that the forms of insect larvæ depend greatly on the group to which they belong. Thus the same tree may harbour larvæ of Diptera, Hymenoptera, Coleoptera, and Lepidoptera; each presenting the form typical of the group to which it belongs.

FIG. 1, Larva of the Cockchafer (Melolontha). (Westwood. Int. to the Modern Classification of Insects, v. 1., p. 194.) 2, Larva of Cetonia. 3, Larva of Trox 4, Larva of Oryctes. 5, Larva of Aphodius. (Chapuis and Candeze, Mem. Soc. Roy. Liege, 1853. 6, Larva of Lucanus. (Packard, "Guide to the Study of Insects," Fig. 403).

If, again, we take a group, such, for instance, as the Lamellicorn beetles, we shall find larvæ extremely similar in form, yet very different in habits. Those for instance of the common cockchafer (Fig. 1) feed on the roots of grass, those of *Cetonia aurata* (Fig. 2) are found in ants' nests; the larvæ of the genus Trox (Fig. 3) on dry animal substances; of Oryctes (Fig. 4) in tan-pits: of Aphodius (Fig. 5) in dung; of Lucanus (the stag-beetle, Fig. 6) in wood.

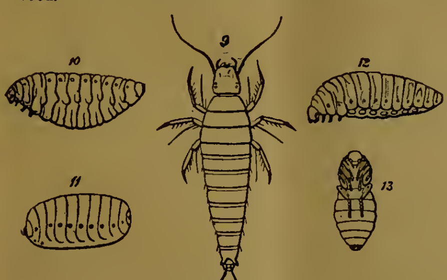

FIG. 9, Larva of Sitaris humeralis. (Fabre, Ann. d. Sci. Nat. Ser. 4, vol. vii.) 10, Larva of Sitaris humeralis, in the second stage. 11, Larva of Sitaris humeralis, in the third stage. 12, Larva of Sitaris humeralis, in the fourth stage. 13, Pupa of Sitaris.

In the present chapter it will be my object to show that the form of the larva depends also very much on its mode of life. Thus, those larvæ which are internal parasites, whether in animals or plants, belong to the vermiform state; and the same is the case with those which live in cells, and depend on their parents for food. On the other hand, larvæ which burrow in wood have strong jaws and generally somewhat weak thoracic legs; those which feed on leaves have the thoracic legs more developed, but less so than the carnivorous species. Now, the Hymenoptera, as a general rule, belong to the first category: the larvæ of the Ichneumons, &c., which live in animals,—those of the Cynipidæ, which inhabit galls,—and those of ants, bees, wasps, &c., which are fed by their parents, are all fleshy, apodal grubs. On the other hand, the larvæ of *Sirex*, which are wood-burrowers, quit the type which is common to the majority of the order, and remain in the egg until they have developed small thoracic legs. Again, the larvæ of the Tenthredinidæ, which feed upon leaves, closely

FIG. 7, Larva of Brachytarsus (Ratzeburg, Forst. Insecten). 8, Larva of Crioceris (Westwood, l.c.) 14. Larva of Sirex (Westwood l.c.) 15. Egg of Rhynchites, showing the parasitic larva in the interior. 16, the parasitic larva more magnified.

resemble the caterpillars of Lepidoptera, even to the presence of abdominal prolegs. There is, however, some little variety in this respect, some species having eleven pairs, some ten, some nine, while the genus *Lyda* has only the three thoracic pairs.

Again, the larvæ of beetles are generally active, hexapod, and more or less flattened: but on the other hand with those species which live inside vegetable tissues, such as the weevils, they are apod fleshy grubs, like those of Hymenoptera. Pl. 2, Fig. 6, represents the larva of

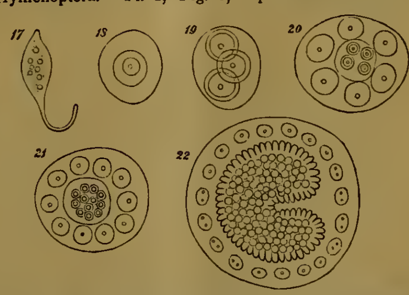

FIG. 17, Egg of Platygaster (after Ganin). 18, Egg of Platygaster showing the central cell. 19, Egg of Platygaster after the division of the central wall 20, Egg of Platygaster more advanced. 21, Egg of Platygaster more advanced. 22, Egg of Platygaster showing the rudiment of the embryo.

the nut-weevil, Balaninus (Pl. 1, Fig. 6), and it will be seen that it closely resembles Pl. 2, Fig. 5, which represents that of a fly (Anthrax), Pl. 1, Fig. 5, and Pl. 2, Figs. 7, 8, and 9, which represent respectively those of a Cynips or gall-fly (Pl. 1, Fig. 7), an ant (Pl. 1, Fig. 8), and wasp (Pl. 1, Fig. 9). Nor is this the only group of Coleoptera which affords us examples of this fact. Thus in the genus Scolytus (Pl. 1, Fig. 4), the larvæ (Pl. 2, Fig. 4),

* Continued from vol. vii. p. 489.

which, as already mentioned, feed on the bark of the elm, closely resemble those just described, as also do those of Brachytarsus (Fig. 7). On the other hand the larvæ of certain beetles feed on leaves, like the caterpillars of Lepidoptera; thus the larva of *Crioceris Asparagi* (Fig. 8), which, as its name denotes, feeds on the asparagus, closely resembles that of certain Lepidoptera, as for instance of *Thecla spini*. A striking illustration of this is afforded by the genus Sitaris (Pl. 3, Fig. 4), a small beetle allied to Cantharis, the blister-fly, and Meloe, the oil-beetle. The habits of this species have been very carefully investigated by M. Fabre.*

The genus Sitaris is parasitic on Anthophora, in the galleries in which it lays its eggs. These are hatched at the end of September or beginning of October; and M. Fabre not unnaturally expected that the young larvæ, which, as already mentioned, are active little

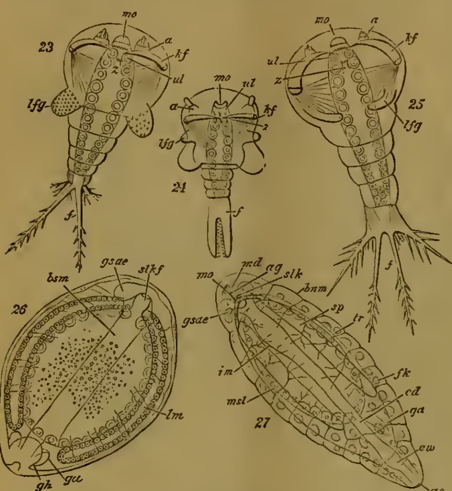

FIG. 23, Larva of Platygaster (after Ganin)—*mo*, mouth; *a*, antenna; *kf*, hocked feet; *r*, toothed process; *lfg*, lateral process; *f*, branches of the tail. 24, Larva of another species of Platygaster. The letters indicate the same parts as in the preceding figure. 25, Larva of a third species of Platygaster The letters indicate the same parts as in the preceding figures. 26, Larva of Platygaster in the second stage—*mo*, mouth; *slkf*, œsophagus; *gsae*, supra-œsophagal ganglion; *lm*, muscles; *bsm*, nervous system; *gagh*, rudiments of the reproductive glands. 27, Larva of Platygaster in the third stage—*mo*, mouth; *md*, mandibles; *gsae*, supra-œsophagal ganglion; *slk*, œsophagus; *ag*, ducts of the salivary glands; *bnm*, ventral nervous system; *sp*, salivary glands; *msl*, stomach; *im*, imaginal discs; *tr*, tracheæ; *fk*, fatty tissue; *ed*, intestine; *ga*, rudiments of reproductive organs; *ew*, wider portion of intestine; *ao*, posterior opening.

creatures with six serviceable legs (Fig. 9), would at once eat their way into the cells of the Anthophora. No such thing: till the month of April following they remain without leaving their birth-place, and consequently without food; nor do they in this long time change either in form or size. M. Fabre ascertained this, not only by examining the burrows of the Anthophoras, but also by direct observation of some young larvæ kept in captivity. In April, however, his specimens at last threw off their long lethargy, and hurried anxiously about their prisons. Naturally inferring that they were in search of food, M. Fabre supposed that this would consist either of the larvæ or pupæ of the Anthophora, or of the honey with which it stores its cell. All three were tried without success. The two first were neglected, and when placed on the latter the larvæ hurried away, or perished in the attempt, being evidently unable to deal with the sticky substance. M. Fabre was in despair: "Jamais experience," he says, "n'a éprouvé pareille déconfiture. Larves, nymphes, cellules, miel, je vous ai tous offert; que voulez-vous donc, bestioles maudites?" The first ray of light came to him from our countryman, Newport, who ascertained that a small parasite found by Léon Dufour on one of the wild bees, and named by him Triungulinus, was, in fact, the larva of the Meloe. The larvæ of Sitaris much resembled Dufour's Triungulinus; and acting on this hint, M. Fabre examined many specimens of Anthophora, and at last found on them the larvæ of his Sitaris. The males of Anthophora emerge from the pupæ before the females, and he ascertained that as they come out of their galleries, the little larvæ fasten upon them. Not, however, for long: their instinct teaches them that they are not yet in the straight path of development; and, watching their opportunity, they pass from the male to the female bee. Guided by these indications, M. Fabre examined several cells of Anthophora: in some, the egg of the Anthophora floated by itself on the surface of the honey; in others, on the egg, as on a raft, sat the still more minute larva of the Sitaris. The mystery was solved. At the moment when the egg is laid, the Sitaris-larva springs upon it. Even while the poor mother is carefully fastening up her cell, her mortal enemy is beginning to devour her offspring. For the egg of the Anthophora serves not only as a raft, but as a repast. The honey, which is enough for either, would be too little for both; and the Sitaris, therefore, in its first meal, relieves itself from its only rival. After eight days the egg is consumed, and on the empty shell the Sitaris undergoes its first transformation, and makes its appearance in a very different form as shown in Fig. 10.

The honey which was fatal before is now necessary; the activity which before was necessary, is now useless; consequently, with the change of skin the active, slim larva changes into a white, fleshy grub, so organised as to float on the surface of the honey, with the mouth below, and the spiracles above the surface; "grâce à l'embonpoint du ventre," says M. Fabre, "la larve est à l'abri de l'asphyxie." In this state it remains till the honey is consumed; then the animal contracts, and detaches itself from its skin, within which the other transformations take place. In the next stage, which M. Fabre calls the pseudo-chrysalis (Fig. 11), the larva has a solid corneous envelope and an oval shape, and in its colour, consistency, and immobility reminds one of a Dipterous pupa. The time passed in that condition varies much. When it has elapsed, the animal moults again, and again changes its form, and assumes that shown in Fig. 12; after this it becomes a pupa (Fig. 13) without any remarkable peculiarities; and finally, after these wonderful changes and adventures, in the month of August the perfect Sitaris (Pl. 3, Fig. 4) makes its appearance.

On the other hand, there are cases in which larvæ diverge remarkably from the ordinary type of the group to which they belong, without, as it seems in our present imperfect state of information, any sufficient reason.

Thus the ordinary type of Hymenopterous larvæ, as we have already seen, is a fleshy apod grub; replaced however in the leaf-eating and wood-boring groups, Tenthredinidæ and Sirecidæ (Fig. 14) by caterpillars, more or less closely resembling those of Lepidoptera. There is, however, a group of minute Hymenoptera, the larvæ of which reside within the eggs or larvæ of other insects. It is difficult to understand why these larvæ should differ from those of Ichneumons, but as will be seen by the accompanying figures, they assume very remarkable and grotesque forms. The first of these curious larvæ was observed by De Filippi,*

* Ann. das. Sc. Nat. V. vii. T. 4. See also Natural History Review, April 1862.

* Ann. and Mag. of Nat. His., 1852.

who had collected some of the transparent ova of *Rhynchites betuleti* and to his great surprise found more than half of them attacked by a small parasite, which proved to be the larva of a minute Hymenopterous insect belonging to the Pteromalidæ. Fig. 15 shows the egg of Rhynchites, with the parasitic larva, which is represented on a larger scale in Fig. 16. Recently, however, this group has been more completely studied by M. Ganin,* who thus describes the development of Platygaster. The egg, as in other allied hymenopterous families, for instance in Cynips, is elongated and club-shaped (Fig. 17). After a while a large nucleated cell appears in the centre (Fig. 18); this is a new formation not derived from the germinal vesicle. This nucleated cell divides (Fig. 19) and subdivides. The outermost cells continue the same process, thus forming an outer investing layer. The central one, on the contrary, enlarges considerably, and develops within itself a number of daughter cells (Figs. 20 and 21), which gradually form themselves into a mulberry-like mass, thus giving rise to the embryo (Fig. 22).

Ganin met with these larvæ in those of a small gnat, Cecidomyia. Sometimes as many as fifteen parasites occurred in one host, but as a rule only one attained maturity. The three species of Platygaster differed considerably in form, as shown in the three following Figs. (23-25). They creep about in the egg by means of the strong hooked feet, *kf*, somewhat aided by movements of the tail. They possess a mouth, stomach, and muscles, but the nervous, vascular, and respiratory systems do not make their appearance until later. After some time the larva changes its skin and assumes the form represented in Fig. 26. In this moult the last abdominal segment of the first larva is entirely thrown off: not merely the outer skin as in the case of the other segments, but also the hypodermis and the muscles. This larva, as will be seen by the figure, is in the form of a barrel or egg, and ·870 mm. in length, the external appendages having disappeared, and the segments being indicated only by the arrangement of the muscles; *slkf* is the œsophagus leading into a wide stomach which occupies nearly the whole body, *s g s a e* is the rudiment of the supraœsophagal ganglia, *b s n* the ventra nervous cords. The ventral nervous mass has the form of a broad band, with straight sides; it consists of embryonal cells, and remains in this undeveloped condition, during the whole larval state.

At the next moult the larva enters its third state, which, however, as far as the external form (Fig. 27) is concerned, differs from the second only in being somewhat more elongated. The internal organs, however, are much more complex and complete. The tracheæ have made their appearance, and the mouth is provided with a pair of mandibles. From this point the metamorphoses of Platygaster do not appear to differ materially from those of other Hymenoptera.

An allied genus, Polynema, has also very curious larvæ. The perfect insect is aquatic in its habits, swimming by means of its wings; flying, if we may say so, under water. It lays its eggs inside those of Dragon flies; and the larva, as shown in Fig. 28, leaves the egg in the form of a bottled-shaped mass of undifferentiated embryonal cells, covered by a thin cuticle, but without any trace of further organisation. Protected by the egg shell of the Dragon fly, the young Polynema is early able to dispense with its own; and bathed in the nourishing fluid of the Dragon fly's egg, it imbibes nourishment through its whole surface, and increases rapidly in size. The digestive canal gradually makes its appearance, the cellular mass forms beneath the original cuticle a new skin, distinctly divided into segments, and provided with certain appendages. After a while the old cuticle is thrown off, and the larva gradually assumes the form shown in Fig. 29. *asch* are the antennal discs, or rudiments of the antennæ, *flsch* of the wings, *bsch* of the legs, *vfg* are lateral projections, *gsch* of the ovipositor, &c, *fk* is the fatty tissue. The subsequent metamorphoses of Polynema offer no special peculiarities.

* Zeits. f. Wiss. Zool., 1869.

From these facts—and, if necessary, many more of the same nature might have been brought forward—it seems to me evident that while the form of any given larva depends to a certain extent on the group of insects to which it belongs, it is also greatly influenced by the external conditions to which the animal is subjected; that it is a function of the life which the larva leads and of the group to which it belongs.

The larvæ of insects are generally regarded as being nothing more than immature states—as stages in the development of the egg into the imago; and this might more especially appear to be the case with those insects in which the larvæ offer a general resemblance in form and structure (excepting of course so far as relates to the wings) to the perfect insects. Nevertheless we see that this would be a very incomplete view of the case The larva and pupa undergo changes which have no relation to the form which they will ultimately assume. With a general tendency, as regards size and the production of wings, to this goal, there are combined other changes bearing reference only to their existing wants and condition. Nor is there in this, I think, anything which need surprise us. External circumstances act on the insect in its preparatory states, as well as in its perfect condition. Those who believe that animals are susceptible of great, though gradual, change through the influence of external conditions, whether acting, as Mr. Darwin has suggested, through natural selection, or in any other manner, will see no reason why these changes should be confined to the mature animal. And it is evident that creatures which, like the majority of insects, live during different parts of their existence in very different circumstances, may undergo considerable changes in their larval organisation, in consequence of forces acting on their larval condition; not, indeed, without affecting, but certainly without affecting to any corresponding extent, their ultimate form.

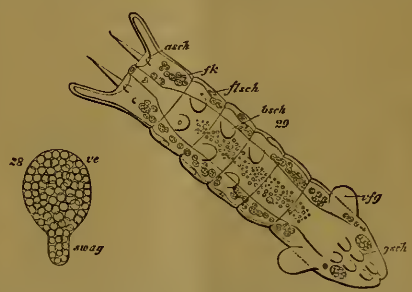

FIG. 28. Embryo of Polynema (after Ganin). 29, Larva of Polynema, *asch*, rudiments of the antennæ; *flsch* of the wings; *bsch* of the eggs; *vfg*. lateral projections; *gsch*, rudiments of the ovipositor; *fk*, latty tissue.

I conclude, therefore, that the form of the larva in insects, whenever it departs from the original vermiform—or the later Campodea—type, depends in great measure on the conditions in which it lives. The external forces acting upon it are different from those which affect the mature form; and thus changes are produced in the young, which have reference to its immediate wants, rather than to its final form.

And, lastly, as a consequence, that metamorphoses may be divided into two kinds, developmental and adaptional.

NOTES

THE following are the names of the fifteen candidates who have been selected by the Council of the Royal Society, for election this year into that body:—William Aitken, M.D., Sir Alexander Armstrong, M.D., K.C.B., Robert Stawell Ball, LL.D., John Beddoe, M.D., Frederick Joseph Bramwell, C.E., Staff-Captain Edward Kilwick Calver, R.N., Robert Lewis John Ellery, F.R.A.S., Lieut.-Col. J. Augustus Grant, C.B., C.S.I., Clements Robert Markham, C.B., George Edward Paget, M.D., George West Royston-Pigott, M.D., Osbert Salvin, M.A., The Hon. John William Strutt, M.A., Henry Woodward, F.G.S., James Young, F.C.S.

THE University of Cambridge has accepted the offer made by Dr. Anton Dohrn of the Zoological Station at Naples, through Dr. Michael Foster and Prof. Newton, of a working table in the laboratory of the station; and last week, on the recommendation of the Board of Natural Sciences, a grace passed the senate without opposition to the effect that from the Worts Travelling Bachelors' Fund the sum of 100*l.* per annum be granted for three years, for the purpose of securing to such members of the University, as the Board shall from time to time nominate, facilities of studying in the station.

WITH reference to a short article entitled "Survival of the Fittest," in NATURE, vol. vii. p. 404, Prof. L. Agassiz writes us that the observations therein attributed to him are taken from an unauthorised newspaper report, from which we infer that he disclaims them.

WITH reference to our report of the American Philosophical Society for August 16, 1872 (NATURE, vol. vii. p. 335), Prof. Cope writes that we have been misinformed as to the date at which his communication on the discovery of Proboscidia in the Wyoming Eocene was communicated to the Society. The paper was not announced to the Society till its meeting on September 20, and was not published till February 6, 1873.

MR. PENGELLY writes us that the specimens referred to by Mr. Everett (NATURE, April 17) did reach him through Mr. Everett's mother, and were duly acknowledged. The labels were rotten with wet, and the specimens consisted of shells and bones, the latter including human teeth and portions of a skull, incisors of some rodent, and a large hog-like molar.

PENIKESE ISLAND, the gift of which for the study of natural history to Prof. Agassiz by Mr. Anderson we have already more than once spoken of, was handed over by the donor on Monday, April 21, in a very simple way, accompanied by some speechmaking. Prof. Agassiz and his generous admirer then met for the first time, and for the first time Agassiz set foot on the future sphere of his labours. The short deed of conveyance was read and handed over, and Prof. Agassiz briefly returned thanks, announcing that he intended to christen the institution to be founded on the island, "The Anderson School of Natural History." Preparations for the school, which will open this summer, will be immediately commenced. Plans have already been drawn for a two-story wooden building 100 ft. long and 25 ft. wide. The lower floor is intended for laboratories and working-rooms, of which there will be eight, with a large hall. The second story will contain twenty-six sleeping-rooms, two bath-rooms, and a large room for the Superintendent of the Institution. Several friends of Mr. Anderson in New York have become interested in the school, and will probably give liberally towards its endowment. The island of Penikese, Penekese, or Penequese, and often called Pune by the pilots, is one of a group of the Elizabethan Isles, lying between Buzzard's Bay and Vineyard Sound, and stretching southward from Cape Cod to a point nearly opposite the coast of Rhode Island. Penikese is just inside and on starboard hand of the entrance to Buzzard's Bay. It is twelve miles from New Bedford. The island is three-fourths of a mile long and half a mile wide, and contains ninety-seven acres of land, some of which is of good quality. A young tree was pointed out that had grown in one season higher than anybody in the party could reach. The surface is hilly, the highest point being about a hundred feet above the water. Mr. Anderson reserves a peninsula of some fifteen acres on the east end of the island, and here he proposes to build a house next year. Prof. Agassiz states that Penikese is a much better location for the school than the one originally contemplated at Nantucket. The school is to be devoted mainly to the study of fish and marine objects in the summer season, and a much larger variety is found in Penikese. The Sound and waters in the vicinity of Nantucket have almost invariably a sandy bottom, while the diversity in marine topography in Buzzard's Bay invites and fosters a corresponding variety of animal and vegetable life.

AT the meeting of the Iron and Steel Institute recently held in London, Mr. Lowthian Bell was elected president, and delivered a very interesting address. He pointed out the great success which had attended the organisation of the society, which although only in the fifth year of its existence, now numbered on its rolls 522 members. He expressed his opinion that the Institute had far from reached its limits. Referring then to the instances which still exist here and there, of a disregard for scientific inquiry, the result, perhaps, of considerable success effected independently of philosophical research, in which cases practical experience, as it is called, is the only rule admitted, Mr. Bell remarked, that on the other hand, abstract science, correct as it may be in every step employed in its elaboration, when introduced into the workshop may be found unable to stand the rude but inevitable test of commercial practicability; hence the necessity of a convenient method of effecting a sound union between these two great principles, and to obtain this was the object of the organisation of the Iron and Steel Institute, where are brought face to face men, some distinguished for their practical knowledge, and others equally eminent for their attachments to scientific observation. He then proceeded to consider the present aspect of foreign competition, and thought the progress in other countries in iron manufacture had arisen from an adaptation of our own appliances, and not from any important discoveries abroad. In speaking of the recent scarcity of coal, although it was his impression that an important addition can and will be made to their present output, he yet contemplated the possibility of a time being now approaching when "any extension of manufacturing operation in this country would have to be regulated, not by the requirements of society for their produce, but by the means our coal mines might possess of furnishing the fuel required. Mr. Bell, after referring to several improvements in the plant and processes for manufacturing iron, looking forward to the future, expressed his opinion that, unless new discoveries of coal be made in Europe, the great rival we have to fear in the iron manufacture is the United States, which possesses unlimited quantities of ores of the finest quality, and such enormous deposits of coal, that our own wealth in that mineral is but comparative poverty. At the proceedings on April 30, a paper by Dr. C. William Siemens, "On the Manufacture of Iron and Steel by Direct Process," was read. Dr. Siemens described his rotative regenerative gas furnace.

A SPECIAL meeting of the Council and Natural History Committee of the Asiatic Society was held at Calcutta a few weeks since, for the purpose of considering Mr. Schwendler's scheme for the establishment of a Zoological Garden in Calcutta. After considerable discussion it was resolved that the Council of the Society should once more record their opinion as to the great advantage to Natural History Science, as well as to the public

which would result from the successful establishment of a Zoological Garden. In addition a Committee was appointed to report on the scheme. Few places are more suitable for the establishment of such gardens than Calcutta—climate, facilities for procuring animals, and an enormous floating population are all in their power. We are glad to learn that several of the native princes have already promised large donations, and that the local and Imperial Governments will give the scheme their support.

DR. SCHOMBURGK's Report on the Botanic Garden at Adelaide, South Australia, gives an interesting view of the usefulness of such an institution in a new country. Although, according to the director, young Australia has very little taste for the science of botany, yet the number of persons who frequent the gardens for the purpose of getting various kinds of information increases yearly. Part of the report deals with the subject of state conservation of forests. In many districts of the colony the supply of wood for timber and fuel appears to be altogether exhausted, or is soon about to become so. The effect of the *déboisement* on the climate is much dreaded by Dr. Schomburgk, and no doubt, even if the belief in a diminution of the rainfall be not well founded, clearing certainly promotes evaporation, and sooner or later brings about the drying up of springs. Various economic plants have been introduced, including esparto (*Macrochloa tenacissima*). The climate allows of the planting out of many palms in the open air, such as *Latania borbonica*, *Rhapis flabelliformis*, *Sabal Blackburniana*, several species of *Chamærops* and others. There are grand possibilities for a well-managed botanic garden in such a climate.

THE third part of Mr. D. G. Elliott's superb "Monograph of the Paradiseidæ or Birds of Paradise," has just been published, it contains six plates beautifully executed by Mr. Wolf and Mr. Smit.

THE first part of a new biological work has recently been published at Moscow, entitled "Pripoda"—popularnoi estestvenno—istoricheski saornik. It contains a paper by M. Severtzoff on the sheep of Asia, but from being written in Russian, it is beyond the reach of most English readers, and would probably be worthy of translation.

LETTERS received from Mr. R. Swinhoe announce his removal from the Consulship of Ning-po to the more northern Chinese port of Che-fow, on the south shore of the Gulf of Petchelee. M. Swinhoe also announces the despatch of a living specimen of the very interesting hornless deer, *Hydropotes inermes*, first described by him in 1870, for the Zoological Society's Menagerie.

WE understand that Dr. John Anderson, F.Z.S., director of the Indian Museum at Calcutta, will return to England in the autumn for a leave of two years.

WE learn from *Sirius* that the Russian Government has devoted 70,000 roubles to the observation of the Transit of Venus, and is to send out twenty-four expeditions to various parts of the world.

FROM *Sirius* we learn that recently 84 pages of a manuscript of Copernicus have been discovered.

THE Archæological Institute of Great Britain and Ireland will hold its annual meeting at Exeter on July 29 and following days. Lord Devon has consented to fill the office of President.

THE Royal Microscopical Society hold a conversazione in the Large Hall, King's College, on Wednesday evening, May 14.

IN reference to the Natural Science Scholarship at Trinity College, Cambridge, to which, as mentioned last week, Mr. Bridge has just been elected, we are informed that Mr. Alfred Milnes Marshall, of St. John's College, was also highly recommended by the examiners for a second scholarship, but the master and seniors decided that only one should be given. Mr. Bridge, we may add, has for some time past, been a non-collegiate member of the University.

A VERY interesting publication is the "Memoir of the Founding and Progress of the U.S. Naval Observatory," at Washington, prepared by Prof. J. E. Nourse, by order of Rear-Admiral B. F. Sands, the present Superintendent of the observatory. The large pamphlet gives details of the history of the observatory from the first attempt in 1810 to move the American Government to take steps to establish a meridian for America, so as to make that country independent of the meridians of Greenwich and Paris, down to the present time, when by the liberality of the Government and the zeal and knowledge of American astronomers and meteorologists, it has become one of the most efficient observatories in the world. The present observatory was founded in 1842, and the first superintendent was the late Commander M. F. Maury, whose successors have been Capt. J. M. Gilliss, Rear-Admiral C. H. Davis, and Rear-Admiral B. F. Sands. In their attempts to render their observations, astronomical, meteorological, and magnetic, as thorough and wide as possible, the officials have been well backed by the American Government, the result being, as we have said, that the observatory is perhaps the most efficient institution of the kind in the world, both with regard to the higher aims and the practical results of the sciences with which it is connected. Every year, almost every month, as the readers of our "Notes" must have seen, are new ramifications being developed, and new means of greater efficiency being added. For the purpose of circulating accurate time, the observatory is connected with all the telegraphic offices in the United States, and every day at 12 o'clock, the exact time is by this means made known throughout the country. At present, as we noted some time ago, there is being constructed for the observatory by Messrs. Clark, of Cambridgeport, at a cost of 50,000 dollars, a refracting telescope of the largest size; and as we also noted several months since, preparations on the most liberal scale are being made for observing the forthcoming Transit of Venus.

A CORRESPONDENT puts the following case:—A strong man is suddenly struck dead by lightning. What has become of the potential energy he possessed the instant before he was struck? To this we have received the following reply:—His potential energy would be where it was before, viz., within the space bounded by his external surface. What the lightning has done has been to destroy the mechanism for realising that potential energy. A small portion of the man's potential energy might have been converted into actual energy by the lightning, as, for instance, in the shape of heat; but the great bulk would be got by anybody who chose to eat his body.

AN International Monument to the late Commodore Maury has been proposed, and there is no doubt his memory well deserves such a tribute. It has been mooted that an appropriate form in which to embody the monument would be a lighthouse on Rocos, which is sighted by all vessels on the route t Rio de Janeiro.

AT a meeting held in Edinburgh last week, it was resolved to appeal to the public for subscriptions in order to procure the erection in Edinburgh of Mrs. D. O. Hill's statue of Dr. Livingstone. The sum proposed to be raised is 3,500*l*.

THE U.S. signal office has begun the publication of a brief monthly review of the weather, in which special attention is, of course, given to the storms that visit the United States. It appears from these that there were enumerated during the month of January twelve storms, during February ten, and during March eleven. The paths pursued by the centres of these storms are classified as follows:—Twenty-one passed from the Upper Mis-

souri Valley, and possibly from Oregon and British Columbia, eastward, over the lakes to Canada or New England; nine passed from the south-west, north and eastward, to the Middle or Eastern States; three passed from the south-west, eastward, to the South Atlantic States, and thence north-eastward; and two passed up north-eastward some distance off the Atlantic coast. Several of these storms divided into two portions, pursuing separate routes; and, with but one or two exceptions, they all increased in severity as they advanced eastward. The rainfall returns show a general deficiency on the Pacific coast; that, however, which was reported in the States east of the Rocky Mountains in March is probably compensated by the excess during January and February. During the entire three months the temperature has been colder than usual—at least for the country east of the Rocky Mountains.

WE have received the programme of the Leeds Naturalist's Field Club for the quarter April to June, from which we see that alternately with "exhibition of specimens and conversation," which takes place once a fortnight, papers on subjects of scientific interest are to be read. Excursions also take place on an average once a fortnight, the first object of the Club being "the minute investigation of the natural history, in all its branches, of the immediate neighbourhood of Leeds, and a more general investigation of the whole of the West Riding." This Society was founded in 1870, and was reorganised on a broader basis in March 1872, and seems to be doing good work.

A CORRESPONDENT writes, asking information with reference to the etymology of the word *aphis*.

THE following additions to the Brighton Aquarium have been made during the past week:—Picked Dogfish (*Acanthias vulgaris*), Larger Spotted Dog-fish (*Scyllium stellare*), Lesser do. (*Scyllium canicula*), Monkfish (*Rhina squatina*), Spotted Rays (*Raja maculata*), Sharp-nosed do. (*Raja lintea*), Streaked Gurnards (*Trigla lineata*), Grey Gurnards (*Triglia gurnardus*), Greater Weevers (*Trachinus draco*), Lesser do. (*Trachinus vipera*), Gemmeous Dragonets (*Callionymus lyra*), Lump Fish (*Cyclopterus lumpus*), Sea Snail (*Liparis vulgaris*), Yarrell's Blenny (*Blenniops ascani*), Sand Smelts (*Atherina presbyter*), Turbot (*Rhombus maximus*), Brill (*Rhombus lævis*), Sail Fluke (*Rhombus punctatus*), Plaice (*Pleuronectes platissa*), Flounders (*Pleuronectes flesus*), Soles (*Solea vulgaris*), Minnows (*Leuciscus phoxinus*), Tench (*Tinca vulgaris*), Masked Crab (*Corystes cassivelanus*), Tube Worms (*Serpula contortuplicata*), Sea Mice (*Aphrodite aculeata*), Sun Starfish (*Solaster papposa*), Mediterranean Corals (*Balanophyllia verrucari*), Golden Cup Coral (*Balanophyllia regia*), Devonshire Cup Coral (*Caryophyllia smithii*), Sea-fingers (*Alcyonium digitatum*), Sea-anemones (various).

THE additions to the Zoological Society's Gardens during the past week include an Indian leopard (*Felis pardus*), two Indian jackals (*Canis aureus*), presented by Capt. Henry; a Malabar Squirrel (*Sciurus maximus*), presented by Mr. Whiteside; three Egyptian cats *Felis chaus* (?) from Cashmere, presented by Capt. J. J. Bradshaw; two Egyptian geese (*Chenalopex ægyptiaca*), presented by Mr. H. W. Thornton; a hawfinch (*Coccothraustes vulgaris*), from the British Isles, presented by the Viscountess Downe; four European Terrapins (*Emys lutaria*) and a green lizard (*Lacerta viridis*, var. *chloronotus*), presented by Lord A. Russell; two black-handed spider monkeys *Ateles melanochir*); a white-throated Capuchin (*Cebus hypoleucus*); a blue-fronted Amazon (*Chrysotis æstiva*); a yellow-fronted Amazon (*C. ochrocephala*), and an orange-winged Amazon (*C. amazonica*), from Cartagena; a crested agouti (*Dasyprocta cristata*) from Colon; an alligator, and a red and yellow macaw (*Ara chloroptera*), from Barauquilla; a golden eagle (*Aquila chrysaëtus*), purchased; a bladder-nosed seal (*Cystophora cristata*), from the North Atlantic, deposited.

ON THE HYPOTHESES WHICH LIE AT THE BASES OF GEOMETRY*

III.—*Application to Space.*

§ 1.—BY means of these inquiries into the determination of the measure relations of an n-fold extent the conditions may be declared which are necessary and sufficient to determine the metric properties of space, if we assume the independence of line-length from position and expressibility of the line-element as the square root of a quadric differential, that is to say, flatness in the smallest parts.

First, they may be expressed thus: that the curvature at each point is zero in three surface-directions; and thence the metric properties of space are determined if the sum of the angles of a triangle is always equal to two right angles.

Secondly, if we assume with Euclid not merely an existence of lines independent of position, but of bodies also, it follows that the curvature is everywhere constant; and then the sum of the angles is determined in all triangles when it is known in one.

Thirdly, one might, instead of taking the length of lines to be independent of position and direction, assume also an independence of their length and direction from position. According to this conception changes or differences of position are complex magnitudes expressible in three independent units.

§ 2.—In the course of our previous inquiries, we first distinguished between the relations of extension or partition and the relations of measure, and found that with the same extensive properties, different measure-relations were conceivable; we then investigated the system of simple size-fixings by which the measure-relations of space are completely determined, and of which all propositions about them are a necessary consequence; it remains to discuss the question how, in what degree, and to what extent these assumptions are borne out by experience. In this respect there is a real distinction between mere extensive relations, and measure relations; in so far as in the former, where the possible cases form a discrete manifoldness, the declarations of experience are indeed not quite certain, but still not inaccurate; while in the latter, where the possible cases form a continuous manifoldness, every determination from experience remains always inaccurate: be the probability ever so great that it is nearly exact. This consideration becomes important in the extensions of these empirical determinations beyond the limits of observation to the infinitely great and infinitely small; since the latter may clearly become more inaccurate beyond the limits of observation, but not the former.

In the extension of space-construction to the infinitely great, we must distinguish between *unboundedness* and *infinite extent*, the former belongs to the extent relations, the latter to the measure-relations. That space is an unbounded three-fold manifoldness, is an assumption which is developed by every conception of the outer world; according to which every instant the region of real perception is completed and the possible positions of a sought object are constructed, and which by these applications is for ever confirming itself. The unboundedness of space possesses in this way a greater empirical certainty than any external experience. But its infinite extent by no means follows from this; on the other hand if we assume independence of bodies from position, and therefore ascribe to space constant curvature, it must necessarily be finite provided this curvature has ever so small a positive value. If we prolong all the geodesics starting in a given surface-element, we should obtain an unbounded surface of constant curvature, *i.e.*, a surface which in a *flat* manifoldness of three dimensions would take the form of a sphere, and consequently be finite.

§ 3. The questions about the infinitely great are for the interpretation of nature useless questions. But this is not the case with the questions about the infinitely small. It is upon the exactness with which we follow phenomena into the infinitely small that our knowledge of their causal relations essentially depends. The progress of recent centuries in the knowledge of mechanics depends almost entirely on the exactness of the construction which has become possible through the invention of the infinitesimal calculus, and through the simple principles discovered by Archimedes, Galileo, and Newton, and used by modern physic. But in the natural sciences which are still in want of simple principles for such constructions, we seek to discover the causal relations by following the phenomena into great minuteness, so far as the microscope permits. Questions

* (Continued from page 17.)

about the measure-relations of space in the infinitely small are not therefore superfluous questions.

If we suppose that bodies exist independently of position, the curvature is everywhere constant, and it then results from astronomical measurements that it cannot be different from zero; or at any rate its reciprocal must be an area in comparison with which the range of our telescopes may be neglected. But if this independence of bodies from position does not exist, we cannot draw conclusions from metric relations of the great, to those of the infinitely small; in that case the curvature at each point may have an arbitrary value in three directions, provided that the total curvature of every measurable portion of space does not differ sensibly from zero. Still more complicated relations may exist if we no longer suppose the linear element expressible as the square root of a quadric differential. Now it seems that the empirical notions on which the metrical determinations of space are founded, the notion of a solid body and of a ray of light, cease to be valid for the infinitely small. We are therefore quite at liberty to suppose that the metric relations of space in the infinitely small do not conform to the hypotheses of geometry; and we ought in fact to suppose it, if we can thereby obtain a simpler explanation of phenomena.

The question of the validity of the hypotheses of geometry in the infinitely small is bound up with the question of the ground of the metric relations of space. In this last question, which we may still regard as belonging to the doctrine of space, is found the application of the remark made above; that in a discrete manifoldness, the ground of its metric relations is given in the notion of it, while in a continuous manifoldness, this ground must come from outside. Either therefore the reality which underlies space must form a discrete manifoldness, or we must seek the ground of its metric relations outside it, in binding forces which act upon it.

The answer to these questions can only be got by starting from the conception of phenomena which has hitherto been justified by experience, and which Newton assumed as a foundation, and by making in this conception the successive changes required by facts which it cannot explain. Researches starting from general notions, like the investigation we have just made, can only be useful in preventing this work from being hampered by too narrow views, and progress in knowledge of the interdependence of things from being checked by traditional prejudices.

This leads us into the domain of another science, of physic, into which the object of this work does not allow us to go to-day.

Synopsis

PLAN of the Inquiry:

I. Notion of an n-ply extended magnitude.
